The prognostic value of FDG-PET has also been reported in patients undergoing allogeneic HCT. In a study in Italy, 46 patients with relapsed HD underwent reduced-intensity allogeneic HCT [54]. Patients with negative FDG-PET had significantly better outcome with a 3-year OS rate of 82% versus 28% ($p = 0.006$) for FDG-PET-positive patients and a 3-year PFS rate of 72% versus 30% ($p = 0.027$). The risk of relapse was significantly higher for FDG-PET-positive patients, 59% versus 27% ($p = 0.066$) for FDG-PET-negative patients. These results emphasize the importance of FDG-PET response in predicting the outcome of both aHCT and allogeneic HCT. Patients with persistent positive FDG-PET after salvage therapy before HCT have a poor outcome, and a trial of new investigational agents such as brentuximab vedotin and bendamustine should be considered. These agents can be used as a potential bridge to transplant.

Timing of transplantation

An important issue concerning aHCT for HD relates to the appropriate time to perform this procedure during the course of disease. Some patients with relapsed HD may be cured with conventional salvage chemotherapy or radiotherapy, and it may be appropriate to delay transplantation until after these approaches fail. Conversely, transplantation should not be delayed to a point when resistance to chemotherapy or poor performance status makes cure unlikely with any approach. Potential times when aHCT for HD can be performed are displayed in Table 56.3. Although data from randomized trials are lacking, results in each situation can be compared with results of conventional salvage therapy.

Failure to attain initial complete remission

HD patients who do not achieve complete remission with initial chemotherapy have a poor prognosis [4] and aHCT may be the only curative treatment for them. Several cooperative groups and institutions have reported results of aHCT for these patients.

The EBMT identified 175 HD patients who failed to achieve an initial complete or partial remission after one or more regimens [55]. The 5-year actuarial OS and PFS were 36 and 32%, respectively (Figure 56.5). OS was significantly better for patients who were transplanted within 18 months of diagnosis. The ABMTR analyzed aHCT results for 122 HD patients who never achieved remission after completing at least one combination chemotherapy regimen [56]. The 3-year OS and PFS were estimated to be 50 and 38%, respectively. OS was significantly worse in patients with systemic symptoms at diagnosis and in patients with a poor performance status at the time of transplant. Other reports of aHCT for primary refractory HD are displayed in Table 56.4.

No randomized trials have compared the results of aHCT with conventional salvage chemotherapy for patients with primary refractory HD, although other comparisons have been performed. At Stanford University, induction failure was defined as progression during initial therapy or relapse within 2 months [16]. Results of aHCT for these patients were compared with those for historical controls who received conventional salvage therapy. The EFS at 4 years was projected to be 52 and 19%, respectively ($p = 0.01$). However, there were no significant differences in OS (44% vs. 38%, respectively, $p = 0.32$). A case–control study from the French database examined the outcome of HD patients who progressed during first-line treatment or within 3 months of completing treatment [17]. OS 6 years from the time of diagnosis was 38% for transplanted patients compared with 29% for patients who received conventional salvage therapy ($p = 0.058$). A retrospective analysis in Cologne, Germany, examined outcomes in 67 patients with primary progressive HD, defined as progression during first-line therapy or within 3 months after initial therapy [57]. The mean survival was 56.2 months for patients treated with aHCT compared with 11.2 months for those who received conventional salvage therapy. The actuarial 5-year OS rates were 53 and 0%, respectively. The use of aHCT was identified as a significant factor associated with improved freedom from treatment failure ($p = 0.031$) and OS ($p = 0.039$). A retrospective analysis by the Gruppo Italiano per lo Studio dei Linfomi (GISL) reviewed the results of therapy in 72 patients with HD who progressed or had minimal response to initial chemotherapy [58]. HDT followed by aHCT was attempted in 27 of these patients. The actuarial 4-year OS was 81% for this group, compared with 38% in patients who received chemotherapy alone ($p = 0.019$).

Interpretation of results of aHCT in these patients is difficult because of different definitions of "primary refractory" and "induction failure." Definitions include patients with disease progression during initial therapy, stable disease after initial therapy, progression within 90 days of completing initial therapy, and partial remission with initial therapy. Patients who progress on primary therapy, and those who have no response, are likely to have a different

prognosis than patients who have a partial remission or near-complete remission. This is supported by French registry data demonstrating significantly worse OS and PFS when aHCT results for primary refractory HD patients were compared with results from patients in first partial remission [59]. Another French study identified 27 HD patients with stage IV disease and/or large mediastinal masses who were in an incomplete response (≥50%) following three cycles of ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine) chemotherapy [60]. This group was treated with aHCT and the 5-year EFS was estimated to be 87%, compared with 61% for control patients treated with conventional therapy ($p = 0.02$). The actuarial 5-year OS rates were 92 and 77%, respectively ($p = 0.2$). Other investigators have also reported good outcomes following aHCT for HD patients in first partial remission [61–63]. It would seem that patients who attain a good partial remission following primary therapy can do well following aHCT, although reports may classify these patients in the category of primary refractory disease.

Interpretation of results is also hampered by the fact that patients may not have biopsy-proven residual disease before transplantation, and that some merely had residual radiographic abnormalities without active disease. It is hoped that the use of modalities such as FDG-PET scans will help with this difficulty. Finally, it is important to recognize that a significant proportion of patients with primary refractory disease will not be able to proceed to transplant and that patients reported in these series may be selected [14,18]. Nevertheless, the results in Table 56.4 appear superior to those attainable with conventional salvage chemotherapy, and aHCT may be the best option for patients who fail to respond to initial chemotherapy. Additional chemotherapy or radiation may be considered prior to HDT for patients with significant tumor burden, whereas other patients with minimal disease remaining after primary therapy should proceed directly to transplantation [55].

First relapse

HDT followed by aHCT for HD is most often considered for patients who relapse following their initial chemotherapy-induced complete remission. Several reports of aHCT in this situation have been published and allow comparison with results of conventional salvage therapy. Selected results of aHCT for HD after first relapse are displayed in Table 56.5, which includes series that specifically address this population of patients [13,15,19,27,31,32,64].

Some of these trials compared the results of aHCT with those of conventional salvage chemotherapy. The duration of initial remission is an important prognostic factor for outcome with conventional salvage chemotherapy for HD [4,18]. In the randomized GHSG trial, HD patients in first relapse were divided into those with early (<12 months) or late (>12 months) relapses [13]. The time to treatment failure at 3 years was estimated to be 41% for early relapse patients treated with aHCT compared with 12% for those who received conventional salvage chemotherapy ($p = 0.008$). OS was estimated to be 43 and 40%, respectively ($p = 0.623$). The actuarial 3-year time to treatment failure for patients with long first remissions was 75% following aHCT, compared with 44% for patients who received conventional salvage chemotherapy ($p = 0.025$). OS survival rates were 93 and 75%, respectively ($p = 0.088$). An analysis by Stanford University compared the outcome of aHCT for patients after first relapse of HD with the results of conventional salvage chemotherapy in historical controls [16]. The 4-year EFS for patients with initial remissions of 12 months or less was estimated to be 56% following aHCT compared with 19% for those who received conventional salvage chemotherapy ($p < 0.01$). OS rates were 58 and 38%, respectively ($p = 0.15$). No significant differences in OS or EFS were seen in patients with longer initial remissions. A retrospective French–Belgian analysis of HD treatment after first relapse found that OS was 69% following aHCT, compared with 55% for patients treated with conventional chemotherapy (p = NS) [15]. Among patients with initial remissions less than 12 months in duration or with stage III–IV disease at relapse, the freedom from treatment failure was estimated to be 64% following aHCT and 40% for those who received conventional chemotherapy. The OS rates were estimated to be 55 and 30%, respectively. A subsequent analysis demonstrated that the actuarial 4-year OS following aHCT was 81% for patients with late relapses as compared with 65% for patients with shorter initial remissions ($p < 0.05$) [65].

[a] Median follow-up 2.3 years.

Other groups have also analyzed transplant outcome in relation to the duration of the first HD remission. A report from the Spanish registry demonstrated that 5-year time to treatment failure was estimated at 57% following aHCT after a first remission of at least 12 months, compared with 43% for those with shorter remissions ($p = 0.0014$) [64]. The OS rates were 67 and 50%, respectively ($p = 0.001$). The Minnesota group showed that 5-year OS following aHCT was estimated to be 60% for those with long initial remission (>12 months) compared with 44% for those with shorter remissions ($p = 0.04$) [24]. At Vancouver the PFS was estimated to be 85% for HD patients treated with aHCT after an initial remission of at least 1 year, compared with 48% for those with shorter remissions ($p = 0.016$) [19]. In contrast, other reports have failed to note statistically significant differences in outcome related to the duration of initial remission [22,31,32,40,66].

Prognostic factors for aHCT after first HD relapse are similar to those reported in Table 56.2. Results from the Spanish registry revealed that the actuarial 5-year OS was 75% for patients who achieved a second remission with conventional salvage therapy prior to aHCT, 43% for patients who were sensitive to salvage therapy, but did not attain a second remission, and 19% for resistant patients [64]. Results from the EBMT and ABMTR also demonstrated prolonged OS in patients who were transplanted in second complete remission, compared with patients who had sensitive relapse, but did not achieve a second remission [27,55].

Although OS advantages have not been demonstrated, most investigators would recommend aHCT for HD patients who relapse within 1 year of attaining remission with initial chemotherapy. There is more controversy regarding the management of patients with longer remissions since a significant proportion may achieve prolonged second remissions with radiation or conventional salvage chemotherapy. It may be reasonable to delay transplantation until second relapse in some patients, although transplantation regardless of length of initial remission is usually advocated [4,13,32,67].

Second or subsequent relapse

Prolonged DFS is unusual following treatment with third-line chemotherapy regimens for HD. No significant differences in time to treatment failure or OS were identified when aHCT and conventional salvage chemotherapy were compared in patients with multiple relapses in the randomized GHSG trial [13]. However, only 24 patients were included in the comparison and most investigators would recommend transplantation for HD patients following a second relapse from chemotherapy.

First remission

Some trials have demonstrated that NHL patients with adverse prognostic characteristics benefit from strategies that employ aHCT in first remission or as part of primary therapy. There is less experience with early aHCT for HD, although a number of variables have been identified that might be used to identify potential candidates [5].

Italian investigators reported results of high-dose chemotherapy followed by aHCT in 22 first remission HD patients [68]. All patients had adverse characteristics at diagnosis and had been treated with mechlorethamine, vincristine (Oncovin), procarbazine, prednisone (MOPP)/ABVD. Their outcome was compared with those of concurrently treated patients with similar characteristics who also achieved complete remission, but did not desire transplantation. Eighteen patients were alive at the time of publication and only one had relapsed. The actuarial survival of transplanted patients was 80% with a median follow-up of 83 months. The actuarial PFS was estimated to be 77%. Only eight of 24 patients who were not consolidated with aHCT were alive and free of disease. A prospective European intergroup trial also evaluated the role of early aHCT for HD [69]. Patients with adverse prognostic characteristics were treated with ABVD or similar regimens. Those in complete or partial remission after four cycles of therapy were randomized to treatment with four additional cycles of therapy or to treatment with HDT followed by aHCT. The 5-year failure-free survival was estimated to be 75% for patients randomized to transplant compared with 82% for patients who continued on chemotherapy ($p = 0.4$). The 5-year OS rates were estimated at 88% in each arm ($p = 0.99$). Results of other phase II trials and retrospective analyses examining results of aHCT for patients with HD in first remission are displayed in Table 56.6. The results suggest that PFS may be prolonged by early transplantation for poor-prognosis HD. However, there is little evidence that OS is prolonged, since transplantation or other salvage therapies can be used at relapse. In addition, most series only report outcomes for the selected poor-prognosis patients who are able to be transplanted. It is likely that many patients with adverse prognostic features do not attain remission or may not be transplanted for other reasons, and this “denominator” is rarely reported [62]. Until prospective trials demonstrate significant advantages for patients undergoing aHCT for HD in first remission, this approach should not be considered standard therapy.

Table 56.6 Results of autologous hematopoietic cell transplantation for Hodgkin disease in first remission

Ref.	*n*	Outcome
9	57	70% 5-yr TTF

Autologous hematopoietic cell transplantation for children

The prognosis for children and adolescents with HD is better than for adults and most are cured with primary therapy. Nevertheless, approximately 10–15% of these patients are not cured and aHCT has been extended to the pediatric population.

A case-matching study from the EBMT compared the results of aBMT in 81 HD patients who were under the age of 16 at diagnosis with results from 81 adults [70]. The median age at the time of transplant was 16.9 years. The PFS (median follow-up 36 months) for pediatric patients was estimated at 39% compared with 48% in adults (median follow-up 34 months) ($p = 0.64$). The patterns of relapse and the incidence of transplant-related toxicities were also similar.

A retrospective study by the University of Nebraska analyzed the results of aHCT in 53 children and adolescents (age ≤21 years) with relapsed and refractory HD [71]. The 5-year failure-free survival and OS were estimated to be 43 and 31%, respectively. No significant differences in outcome were observed when younger pediatric patients were compared with adolescents, and no significant differences in outcome were observed when these patients were compared with a historical control group of patients over the age of 21 years who were transplanted during the same period. A similar analysis by Stanford University examined the results of aHCT in 41 pediatric patients with relapsed and refractory HD [72]. The median age was 18 years. The actuarial 5-year PFS and OS were 63 and 68%, respectively.

Results of salvage therapy for pediatric patients with relapsed and refractory HD following treatment in German–Austrian trials were analyzed [73]. The median age at the time of relapse or progression was 14.7 years. The actuarial 10-year OS was 51% for patients treated with aHCT following first recurrence. These results were similar to those for children who received conventional salvage chemotherapy. However, the 6-year OS of children who were transplanted after a second recurrence was estimated to be 52%, compared with 29% for those receiving conventional treatment ($p = 0.04$). A retrospective study by the United Kingdom Children’s Cancer Study Group also examined results of aHCT for childhood HD [74]. The median age of transplanted patients was 12 years. When results for patients treated with aHCT were compared with those for controls who received conventional salvage chemotherapy after first relapse, there were no significant differences in survival. However, patients with primary refractory disease had significantly longer survival following aHCT.

Prolonged PFS can be seen after aHCT for children and adolescents with relapsed and refractory HD and the results are comparable to those for adults. The use of aHCT appears to be justified, particularly in patients with refractory disease and those with multiple relapses. Long-term growth and development are normal, although delayed onset of ovarian function has been observed [71,74]. Of greater concern are reports of respiratory complications [72] and myelodysplastic syndrome (MDS) and acute myeloid leukemia (AML) following aHCT for HD in children [71,74]. Recently, the long-term outcome of 144 children with HD who underwent HDT and aHCT at Stanford University was reported [75]. At a median follow-up of 10.2 years, the 10-year cumulative incidence of death from HD and other causes was 21.7 and 12.7%, respectively. The risk ratio for second malignancies was 8.0 compared with the general population and 1.5 compared with HD patients not undergoing aHCT. Hence children who are survivors of aHCT may be at increased risk of death from HD and other causes compared with the general population, but not compared with the HD population as a whole.

Transplantation for elderly patients

Data from the CIBMTR indicate that 26% of patients treated with aHCT between 2001 and 2004 were older than 60 years of age [76]. Age was not a significant prognostic factor in the majority of trials evaluating results of aHCT for HD, although relatively few patients over the age of 60 years were included, and they may be highly selected. In one report, patients who were ≥45 years of age had significantly worse EFS and OS, however [23].

Most reports of aHCT in the elderly have included patients with a variety of hematologic malignancies and have not reported separate results for HD patients. Results from Stanford showed that regimen-related toxicity and EFS were worse in patients over the age of 50 years who underwent aHCT [77]. Similar results have been reported for older NHL patients [78].

Patients over the age of 60 years can have prolonged failure-free survival following aHCT for relapsed and refractory HD. Although toxicity may be greater, patients should not be excluded from treatment based upon age alone. It may be appropriate to perform more extensive pre-transplant tests of cardiac, pulmonary, and renal function in these patients [78].

Transplantation for HIV-associated Hodgkin disease

Although HD is not an AIDS-defining illness, the incidence of HD is increased 8–10-fold in patients infected with the human immunodeficiency virus (HIV). Highly active antiretroviral therapy (HAART) has changed the natural history of HIV infection and it now is possible for patients with HIV-related HD to receive the same primary chemotherapy treatment that HIV-negative individuals receive.

Earlier results for HDT and aHCT in HIV-associated HD were limited to only a few patients and included patients with HIV-associated NHL. Investigators in Paris reported the results of aHCT in four patients with relapsed HIV-associated HD [79]. All patients received HAART before transplantation and were continued on HAART during hematopoietic cell collection, during and after transplantation. Three patients were alive in complete remission at 4, 13 and 15 months after transplant. An Italian group described results of aHCT in four patients with relapsed and refractory HIV-associated HD [80]. All patients received HAART during treatment. Two patients with relapsed HIV-associated HD were treated with aHCT at the City of Hope [81]. Patients received HAART and had to be free of opportunistic infections for 1 year. The patients were reported to be alive and in remission at 56 and 61 months following HCT.

Recent studies have shown that the outcome of HDT and aHCT for patients with HIV-associated lymphoma are similar to those for HIV-negative patients with lymphoma. Long-term results from the Italian Cooperative Group included 50 HIV-positive HAART-responding patients with refractory/relapsed lymphoma, 38% of whom had HD [82]. At a median follow-up of 44 months, the DFS and OS were 74 and 75%, respectively. Low CD4 count, marrow involvement, and poor performance status independently affected survival. Another study in Spain reported the results of HDT and aHCT in 68 patients with HIV-related lymphoma including 18 patients with HD [83]. Non-relapse mortality (NRM) was 7.5% at 12 months after aHCT, mainly due to bacterial infections. At a median follow-up of 32 months, DFS and OS were 56 and 61%, respectively. These findings were supported by a retrospective analysis by EBMT comparing survival between HIV-positive and -negative lymphoma patients undergoing HDT and aHCT that included 53 patients (66% NHL and 34% HD) within each cohort [84]. Both groups were comparable except for a higher proportion of males and mixed cellularity HD. Incidence of relapse, OS, and PFS were similar in both cohorts. A higher NRM within the first year after aHCT was observed in the HIV-positive group (8% vs. 2%), predominantly because of early bacterial infections, although this was not statistically significant and did not influence survival.

These results demonstrate that peripheral blood hematopoietic cells can be collected in HIV-infected individuals on HAART, and that aHCT can be performed in selected individuals. HIV-related lymphoma patients should be considered for aHCT using the same criteria as for HIV-negative patients. Potential candidates for aHCT should be entered in clinical trials or referred to centers with experience in this patient population.

Late events

Increasing numbers of people are long-term survivors after aHCT for HD and other hematologic malignancies. There are several reports on quality of life after HCT for hematologic malignancies, although no reports have dealt exclusively with outcomes following aHCT for HD alone.

Long-term follow-up of HD patients treated with aHCT in British Columbia demonstrated that 89% had a performance level of at least 90% [36]. Nevertheless, some patients remained on disability and others described significant levels of anxiety and depression. A survey conducted by the International Bone Marrow Transplant Registry and the ABMTR showed that transplant survivors were more likely to report poorer health than controls and reported more problems with fatigue, sleep, and sexual function [85]. Survivors were also more likely to report problems with anxiety, depression, and social functioning. Patients with HD who had been treated with aHCT formed a relatively small percentage of patients in this cohort, however. A similar survey of long-term function following aHCT was conducted in Germany [86]. Patients with HD represented only a small percentage of patients in this survey also. Most patients (67%) rated their global quality of life as good to excellent, and scores improved over time. The majority of patients had returned to their former employment, although difficulty with holding a job has been reported in other studies [87]. Sexual dysfunction was commonly observed.

Patients who undergo aHCT for HD are at risk for late relapse. Although some series have not reported late relapses, others have demonstrated that patients continue to be at risk of relapse for long periods. Relapse more than 7 years following aHCT has been reported [9,36]. These results indicate that life-long follow-up is necessary after aHCT for HD.

The Bone Marrow Transplant Survivor Study (BMTSS) examined long-term outcomes in patients who had survived at least 2 years after aHCT [87]. Patients transplanted for HD had a 28.2-fold risk of late death in comparison with the general population. This risk included relapse and non-relapse causes of death. A nation-wide study of patients undergoing aHCT in Finland noted that patients who had received aHCT for HD had an 8.1% incidence of NRM [88].

A large number of reports have described the occurrence of secondary MDS and AML following aHCT for both HD and NHL [89]. The 5-year risk of developing AML or MDS following aHCT for HD ranged between 4 and 15%. This complication has been observed within months of the transplant. Risk factors that have been reported to be associated with the development of post-transplant MDS/AML include age, extent of prior therapy with alkylating agents, use of total-body irradiation conditioning, or prior use of radiotherapy, history of splenectomy, and use of autologous PBHCT compared with autologous BMT.

There is evidence that the risk of secondary MDS/AML following aHCT for HD is largely related to treatment administered prior to transplant rather than the high-dose conditioning regimen itself. An analysis in Vancouver did not find an increased risk of secondary AML or other malignancies when HD patients who had received aHCT were compared with others who only received conventional chemotherapy [90]. Investigators have also used fluorescence in situ hybridization (FISH) analysis to demonstrate that the cytogenetic abnormalities present in post-transplant MDS/AML can be detected in stored pre-transplant blood or marrow samples from patients with HD [91]. This observation led to the recommendation that cytogenetic analysis should be performed on bone marrow from all patients prior to hematopoietic stem cell collection. In addition, most studies of post-transplant MDS/AML have identified abnormalities of chromosomes 5 and 7 that are associated with typical alkylating agent-based therapy administered prior to aHCT. The short latency period between aHCT and development of MDS/AML in many cases also suggests that malignancy results from prior therapy and not the high-dose chemotherapy regimen.

The occurrence of solid tumors has also been described following aHCT for HD. The 15-year cumulative risk of developing a solid tumor was estimated to be 3.2% following aHCT for HD in the analysis in British Columbia [90].

Other late complications of aHCT for HD include infections [9,27,32,66], cardiac complications [37,66], and pulmonary complications [9,27,37]. The BMTSS found that the risk of late mortality from cardiac dysfunction was increased 4.3-fold and the risk from pulmonary compromise was increased 29.1-fold in survivors of aHCT for HD [87]. Virtually all women will develop amenorrhea following aHCT for HD, although return of ovarian function is not unusual. Successful pregnancies, both assisted and unassisted, have been described following aHCT for HD [41,66], and patients should be counseled about the need for contraception.

Management of relapse

A significant proportion of patients will relapse following aHCT for HD. The median survival following disease progression after aHCT has been reported to be less than 12 months in some series, although some reports show a better prognosis [92,93]. Options are frequently limited because of prior therapy, low blood counts, and poor performance status. Radiation therapy should be considered for patients with localized relapse. High response rates and occasional long-term remissions have been noted with single-agent vinblastine [66,94], and patients will often respond to other conventional salvage regimens for HD [95].

More recently, new agents have been shown to provide effective salvage therapy for relapsed HD post-aHCT. Brentuximab vedotin is an antibody–drug conjugate that selectively delivers monomethyl auristatin E, an antimicrotubule agent, into CD30 express cells. Since CD30 is expressed on malignant Hodgkin Reed–Sternberg cells and has limited expression on normal cells, CD30 is an attractive target for anti-HD therapy. In a phase I dose-escalation trial that enrolled 45 patients with relapsed or refractory CD30$^+$ hematologic malignancies, objective responses were observed in 17 patients and tumor regression was observed in 86% of evaluable patients. A total of 73% of the patients had undergone aHCT [96]. A pivotal phase II study of 102 HD patients with relapsed and refractory disease after aHCT showed an overall response of 75%, with complete remission in 34% of the patients [47] The estimated 12-month survival was 89% and the median PFS for all patients was 5.6 months. The median duration of response for those who achieved complete response was 20.5 months. The treatment was well tolerated and the most common treatment-related adverse events were peripheral sensory neuropathy, nausea, fatigue, neutropenia, and diarrhea.

Panobinostat, a potent pan-deacetylase inhibitor, is another new agent for the treatment of relapsed HD post-aHCT. In a phase II study, 129 heavily pretreated patients with a median of four prior systemic regimens and 41% refractory to chemotherapy were enrolled [97]. Panobinostat 40mg was administered orally three times per week. Tumor reduction was observed in 74% with an objective response of 27%. The median duration of response was 6.9 months and median PFS was 6.1 months. The estimated 1-year OS was 78%. Non-hematologic toxicities include nausea, diarrhea, and fatigue. Grade III–IV thrombocytopenia, anemia, and neutropenia were manageable.

Bendamustine, a bifunctional alkylating agent, was evaluated in a phase II trial in 36 patients with relapsed/refractory HD who were ineligible for aHCT or had relapsed after aHCT [98]. The median number of prior regimens was four and 75% had relapsed after aHCT. Patients received bendamustine at 120mg/m^2 for two consecutive days every 28 days for six cycles. Thirty-four were evaluable for response and the overall response rate was 53%, including 33% complete response and 19% partial response. Responses were seen in patients with refractory disease and also in patients with prior aHCT and allogeneic HCT; however, no response was seen in patients who relapsed within 3 months of aHCT. The median duration of response was 5 months. Similar results were reported by the Italian group for 41 patients, including 85% relapsed after aHCT [99]. The overall response rate was 58% with 31% complete response. Eight responding patients subsequently underwent allogeneic HCT. Median PFS and OS exceeded 11 and 21 months respectively. Therefore, bendamustine may be used in palliative therapy in addition to salvage therapy before allogeneic HCT.

Some patients may be candidates for a second transplant. The EBMT reported that 50% of patients were alive and in remission 2 years after a second aHCT for HD [100]. Others have reported similar results [95]. A report from the IBMTR analyzed results of allogeneic HCT in 114 patients, including 35 with HD, who relapsed after aHCT for lymphoma [101]. All patients received high-dose myeloablative conditioning, and some received unrelated or mismatched transplants. The 100-day mortality rate was 21% and the 5-year cumulative incidence of disease progression was 70%. The 5-year actuarial survival was 24% and no evidence of a survival plateau was noted. RIC followed by allogeneic HCT has also been used to decrease the transplant-related mortality of allogeneic HCT for HD patients with a prior aHCT (see below). At the M.D. Anderson Cancer Center, the 18-month OS and PFS were estimated to be 61 and 32%, respectively, in a cohort of 30 HD patients (75% with a prior aHCT) who received reduced-intensity allogeneic HCT [102]. The 3-year probability of PFS was estimated to be 8% for patients with HD in a series of patients from several institutions who were treated with a reduced-intensity allogeneic HCT after relapsing from a prior transplant [103]. A prospective trial in Spain examined the use of reduced-intensity allogeneic HCT in 29 HD patients who had progressed after aHCT [104]. The actuarial 2-year OS and EFS were 52 and 23%, respectively. These values were 75 and 50%, respectively, for patients whose remission duration following aHCT was at least 12 months.

Source of hematopoietic cells

Most autologous HCT procedures in North America and Europe are now performed with mobilized peripheral blood hematopoietic cells, and autologous BMT is rarely performed [8,76]. Hematopoietic recovery is more rapid following autologous PBHCT and this approach allows cells to be collected without general anesthesia. Most importantly, this approach allows the use of HDT in patients whose marrow cannot be harvested due to tumor contamination or prior radiation.

Results from the series of aHCT for HD displayed in Table 56.1 have not shown differences in survival when results of autologous PBHCT and autologous BMT were compared. A Spanish registry analysis showed that the 5-year time to treatment failure was estimated to be 41% for HD patients treated with autologous BMT, compared with 55.3% for patients who were treated with autologous PBHCT (p = 0.007) [9]. These differences were not significant in the multivariate analysis, however. In contrast, the analysis in Vancouver showed that first-relapse HD patients treated with autologous PBHCT had inferior PFS to recipients of autologous BMT (p = 0.04) [36]. Again, these differences were not significant in the multivariate analysis.

An EBMT matched-pair analysis compared outcomes of autologous PBHCT and autologous BMT for HD patients [105]. The actuarial 4-year PFS was 52% following BMT compared with 38% following PBHCT (p = 0.0082). The actuarial OS rates were 65 and 53%, respectively (p = 0.0198). A single-center matched-pair analysis at University College Hospital in London also compared outcomes of autologous BMT and PBHCT for HD [106]. The 3-year PFS was estimated to be 59% following autologous BMT and 58% for those who received autologous PBHCT (p = 0.255). The 3-year OS rates were 69 and 78%, respectively (p = 0.078).

Prospective trials in cohorts containing patients with both HD and NHL have also compared outcomes in relation to hematopoietic cell source [107–109]. No significant differences in survival were noted, although improvements in secondary outcomes such as engraftment rate, duration of hospital stay, costs, and quality of life have been described in patients treated with autologous PBHCT. Therefore, the use of autologous PBHCT is now preferred owing to secondary advantages associated with ease of collection and engraftment rate.

Allogeneic hematopoietic cell transplantation

The use of allogeneic HCT may provide additional antitumor activity compared with aHCT, but is associated with a higher NRM. It has also been suggested that allogeneic HCT might correct the lifelong immunologic defects seen in HD patients. Allogeneic HCT may also result in a graft-versus-Hodgkin effect similar to the graft-versus-leukemia effect observed after allogeneic HCT for leukemia. Although it is unknown whether infused Reed–Sternberg cells are clonogenic, the use of allogeneic donors also eliminates the risk of reinfusing malignant cells. Allogeneic HCT may be considered for patients with inadequate hematopoietic cell collections or for patients with dysplastic bone marrow or cytogenetic bone marrow abnormalities.

The role of allogeneic HCT for HD is controversial. Results of myeloablative allogeneic HCT are poor, although most series have been composed of patients who were extensively pretreated and those with advanced chemoresistant disease [110,111]. The actuarial 3-year DFS was 15% in 100 patients with advanced HD reported to the IBMTR who underwent myeloablative allogeneic BMT from matched siblings [111]. The 3-year risk of treatment-related mortality was 61%. Factors associated with treatment failure include older age, poor performance status, and recent infection. The 4-year actuarial PFS and NRM were 15 and 48%, respectively, following myeloablative allogeneic HCT in a series of 45 patients reported to the EBMT [112]. The results of allogeneic and autologous HCT for HD have been compared retrospectively. A case-matching analysis from the EBMT identified no significant differences in PFS, OS, relapse, or transplant-related mortality when autologous and allogeneic HCT for HD were compared [112].

At the Johns Hopkins Oncology Center, patients with relapsed and refractory HD were preferentially assigned to receive allogeneic HCT if they had a matched sibling donor and were under the age of 56 years [113]. Patients were otherwise treated with aHCT. A retrospective comparison revealed no significant differences in relapse, EFS, or OS between groups. Investigators in Seattle compared the outcome of allogeneic HCT and aHCT for HD [110]. The relapse rate following allogeneic HCT was lower (45% vs. 76%, p = 0.05), although OS differences were not observed because of higher transplant-related mortality in allogeneic HCT. A more recent EBMT analysis evaluated the outcome of 167 patients with HD who were treated with allogeneic HCT [114]. The donor was a human leukocyte antigen (HLA)-identical sibling in 81.5% of cases. The 4-year PFS and OS were estimated to be 15.5 and 24.7%, respectively. The procedure-related mortality was estimated to be 51.7% at 4 years. A matched-pair analysis demonstrated that aHCT was associated with superior PFS compared with allogeneic HCT.

Graft-versus-Hodgkin disease (GVHL)

Some comparisons have demonstrated that the rate of relapse is lower after allogeneic HCT for HD compared with aHCT [110,112,113]. The data supporting the existence of a GVHL effect derived from the response observed either after donor lymphocyte infusions (DLIs) or after the development of graft-versus-host disease (GVHD).The existence of a GVHL effect is supported by reports of response rates of 3055% after donor leukocyte infusions [115–117]. In a large EBMT retrospective study, DLIs were administered to 64 patients at a median of 6 months (range 1–38 months) for persistent or progressive disease following RIC allogeneic HCT. The response rate was 32% and the median OS following DLI was 20 months. In a subset of 18 patients receiving DLI without additional chemotherapy, the response rate was 44% [118]. Similar results were reported from the M.D. Anderson Cancer Center in 27 patients who developed progressive disease after T-repleted allogeneic HCT. Ten of 27 patients (37%) had a complete or partial response and the median duration of response was 7.5 months (range 0.5–20 months) [119]. Not only has DLI been shown to induce remission, it also has been shown to reduce relapse risk following T-depleted allogeneic HCT. In another study in the United Kingdom, 76 patients with multiple relapsed or refractory HD underwent allogeneic HCT that incorporated in vivo T-cell depletion [120]. DLIs were given in a dose-escalating fashion to 22 patients for mixed chimerism and to 24 patients for relapse. Nineteen of 22 patients (86%) receiving DLI for mixed chimerism converted to full donor status. The 4-year relapse incidence was 5% in these patients compared with 43% in the group with full donor chimerism (p = 0.00071). For those 24 patients receiving DLI for relapse, the response rate was 79% with a 4-year OS of 59%. These results suggest that preemptive DLI based on mixed chimerism may reduce relapse risk following T-depleted allogeneic HCT.

There is also evidence that relapse rates may be lower in patients who develop GVHD [112,121]. An EBMT analysis of 168 HD patients treated with allogeneic HCT found that the development of chronic GVHD significantly decreased the incidence of relapse, which translated into a trend for a better PFS with no impact on NRM [121]. Similar results were reported by the Gruppo Italiano per il Trapianto di Midollo Osseo (GITMO) on 122 patients who underwent allogeneic HCT following relapse post-aHCT. They found that patients with chronic GVHD experienced a significantly better OS ($p < 0.001$) and PFS ($p = 0.024$) compared with those without it or with acute GVHD [122].

Reduced-intensity conditioning followed by allogeneic transplantation

Several groups of investigators have explored the use of RIC allogeneic HCT for HD to exploit potential GVHL effects and to reduce transplant-related mortality [102,104,116,123,124]. These studies have shown the feasibility of this approach in patients who have relapsed after aHCT and in patients who are not candidates for allogeneic HCT using conventional myeloablative regimens. A variety of conditioning regimens have been used from non-myeloablative (fludarabine 90mg/m^2 and TBI 200Gy) to RIC regimens such as fludarabine and melphalan with or without alemtuzumab.

The largest series of RIC and allogeneic HCTs for HD was initially reported by the EBMT [125]. Fifty-two patients were conditioned with a variety of regimens, although the majority received fludarabine-based treatments. The 2-year PFS and OS were estimated to be 42 and 56.3%, respectively. The 1-year transplant-related mortality was 17.3%. Updated results in 285 patients were subsequently published [118]. Most had chemosensitive disease and 80% had prior aHCT. The 1-year TRM was low at 11%, but the 5-year progression rate was 59% without a plateau on the progression curve. The 3-year OS and PFS were 29 and 25%, respectively. The only factor that was significantly associated with DFS and OS was chemosensitivity prior to transplant (Figure 56.6).

Encouraging results of RIC and allogeneic HCT for HD have recently been reported from registry data and also single-center studies. The GEL/TAMO and the Lymphoma Working Party of EBMT reported a phase II trial of allogeneic HCT in 78 patients with relapsed HD (unrelated donors = 23) [126]. Fifty were in complete or partial remission and 28 had stable disease. Fludarabine 150mg/m^2 and melphalan 140mg/m^2 were used as conditioning regimen. Antithymocyte globulin was added for GVHD prophylaxis in recipients of unrelated donor transplants. The NRM was 15% at 1 year. Relapse was the major cause of treatment failure. The PFS rate was 48% at 1 year and 24% at 4 years. Chronic GVHD was associated with a lower incidence of relapse. Patients who were transplanted in complete remission had a significantly better outcome with an OS rate of 71% at 1 year and 43% at 4 years .Refractory disease and poor performance status were associated with significantly worse survival. There was no difference in survival between recipients of match-related and unrelated donors. CIBMTR analyzed the outcome of 143 patients undergoing unrelated donor RIC/non-myeloablative stem cell transplantation (NST) for relapsed/refractory HD [127]. Various conditioning regimens were used. Patients were heavily pretreated with ≥3 prior regimens and 89% had prior aHCT. With a median follow-up of 25 months, the probability of TRM at day 100 and 2 years was 15 and 33%, respectively. The 2-year PFS and OS were 20 and 37%, respectively. Extranodal disease and poor Karnofsky Performance Score (KPS) were significant risk factors for TRM and survival. Relapse and infection were the most common causes of death.

Results from single-center experiences showed a lower incidence of TRM. At the M.D. Anderson Cancer Center, 40 patients with relapsed and refractory HD were treated with RIC allogeneic HCT (matched sibling $n = 20$; matched unrelated donor $n = 20$) [102]. The conditioning regimens consisted of fludarabine plus cyclophosphamide (± antithymocyte globulin), and fludarabine plus melphalan. The actuarial PFS and OS at 18 months were 32 and 61%, respectively. The cumulative incidence of progressive disease was 55%. The OS at 18 months was estimated to be 73% for patients who received fludarabine–melphalan compared with 39% for patients treated with fludarabine–cyclophosphamide ($p = 0.03$). An update in 58 patients receiving fludarabine and melphalan showed a low incidence of TRM of 7% at day 100 and 15% at 2 years [128]. At a median follow-up of 2 years, projected 2-year overall and PFS were 64% and 32%, respectively, with 2-year disease progression/relapse rate of 55%. There was no statistical difference in survival between matched related and unrelated donors transplants. Investigators in the United Kingdom reported results of RIC allogeneic HCT (matched sibling $n = 31$; matched unrelated donor $n = 18$) in 49 patients with multiply relapsed HD [116]. The majority (90%) had progressed after a previous aHCT. The conditioning regimen consisted of fludarabine, melphalan, and alemtuzumab. The 4-year PFS and OS were estimated to be 39 and 55.7%, respectively. Patients in complete remission at the time of transplant had significantly better PFS ($p = 0.0389$) and OS ($p = 0.0398$) compared with patients in partial remission or with refractory disease. PFS was also poorer in patients with a history of aHCT ($p = 0.0267$). Their updated results showed that alemtuzumab significantly reduced the risk of GVHD without impact on survival outcome and durable response to DLI was seen following the inclusion of alemtuzumab in the conditioning regimen [129]. Baron et al. (see earlier) reported results or RIC allogeneic HCT in 35 HD patients who had failed a previous transplant [103]. The conditioning regimen consisted of fludarabine and 2Gy TBI in the majority of patients. The actuarial 3-year PFS and OS were 8 and 35%, respectively.

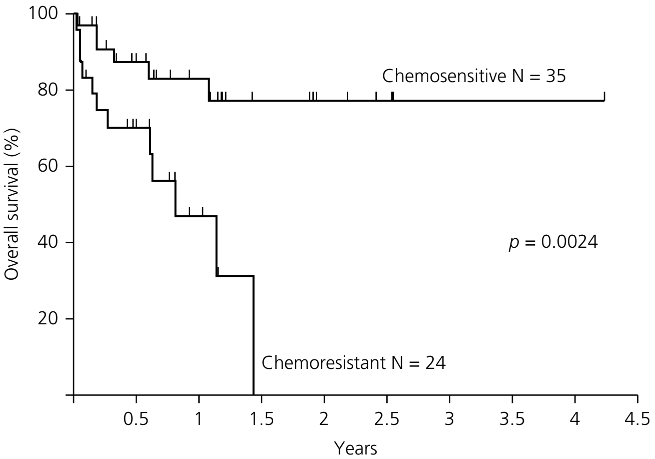

Figure 56.6 Overall survival of patients with chemosensitive or chemoresistant Hodgkin disease following non-myeloablative conditioning. Source: Schmitz et al. 2004 [123]. Reproduced with permission of Elsevier.

Investigators in Spain have also reported on the results of RIC allogeneic HCT (matched sibling $n = 37$) in 40 patients with relapsed or refractory HD [104]. The majority ($n = 29$) had been treated previously with aHCT. Conditioning consisted of fludarabine and melphalan. The 2-year PFS and OS were estimated to be 32 and 48%, respectively. Resistant disease at the time of transplant was associated with significantly worse PFS and OS. Similar outcomes, including the adverse influence of chemotherapy resistance, have been reported by other groups using RIC allogeneic HCT for HD [124].

A comparative analysis of allogeneic HCT with conventional salvage chemotherapy for relapsed HD after aHCT was performed by the retrospective analysis of 185 patients by the Italian investigators [122]. Of 185 patients, 122 found donors (related $n = 55\%$, unrelated $n = 32\%$ and haploidentical $n = 13\%$) and 63 did not. There were no differences in clinical characteristics between the two groups. At a median follow-up of 48 months, the 2-year PFS and OS were better in the donor group (39.3% vs. 14.2% and 66% vs. 42%, respectively, $p < 0.001$). In multivariate analysis, having a donor was significant for better PFS and OS ($p < 0.001$). Patients who were transplanted in complete remission showed a better PFS and OS. This study supports the role of allogeneic HCT in patients with HD who had relapsed after aHCT.

The comparative analysis of allogeneic HCT after RIC or conventional high-dose conditioning in patients with relapsed or refractory HD was reported by the EBMT [121]. In this study, the clinical outcomes of 89 patients who underwent RIC allogeneic HCT were compared with the outcomes of 79 patients who underwent conventional high-dose allogeneic HCT. The two groups were comparable except that more patients in the high-dose group were transplanted in earlier years and had received bone marrow. RIC patients were more heavily pretreated, and more patients had relapsed after a prior aHCT (61.8% vs. 40.5%, $p = 0.005$). There was no difference in hematopoietic recovery or the incidence of GVHD between the two groups. However, the NRM was significantly decreased in the RIC group (48% vs. 24%, hazard ratio 2.85, $p < 0.001$). The 5-year OS was also better in the RIC group and there was a trend for better 5-year PFS in the RIC group. Patients who developed chronic GVHD had a significantly decreased risk of relapse, which translated into a trend for a better PFS (Figure 56.7). In another study reported from the United Kingdom, the outcome

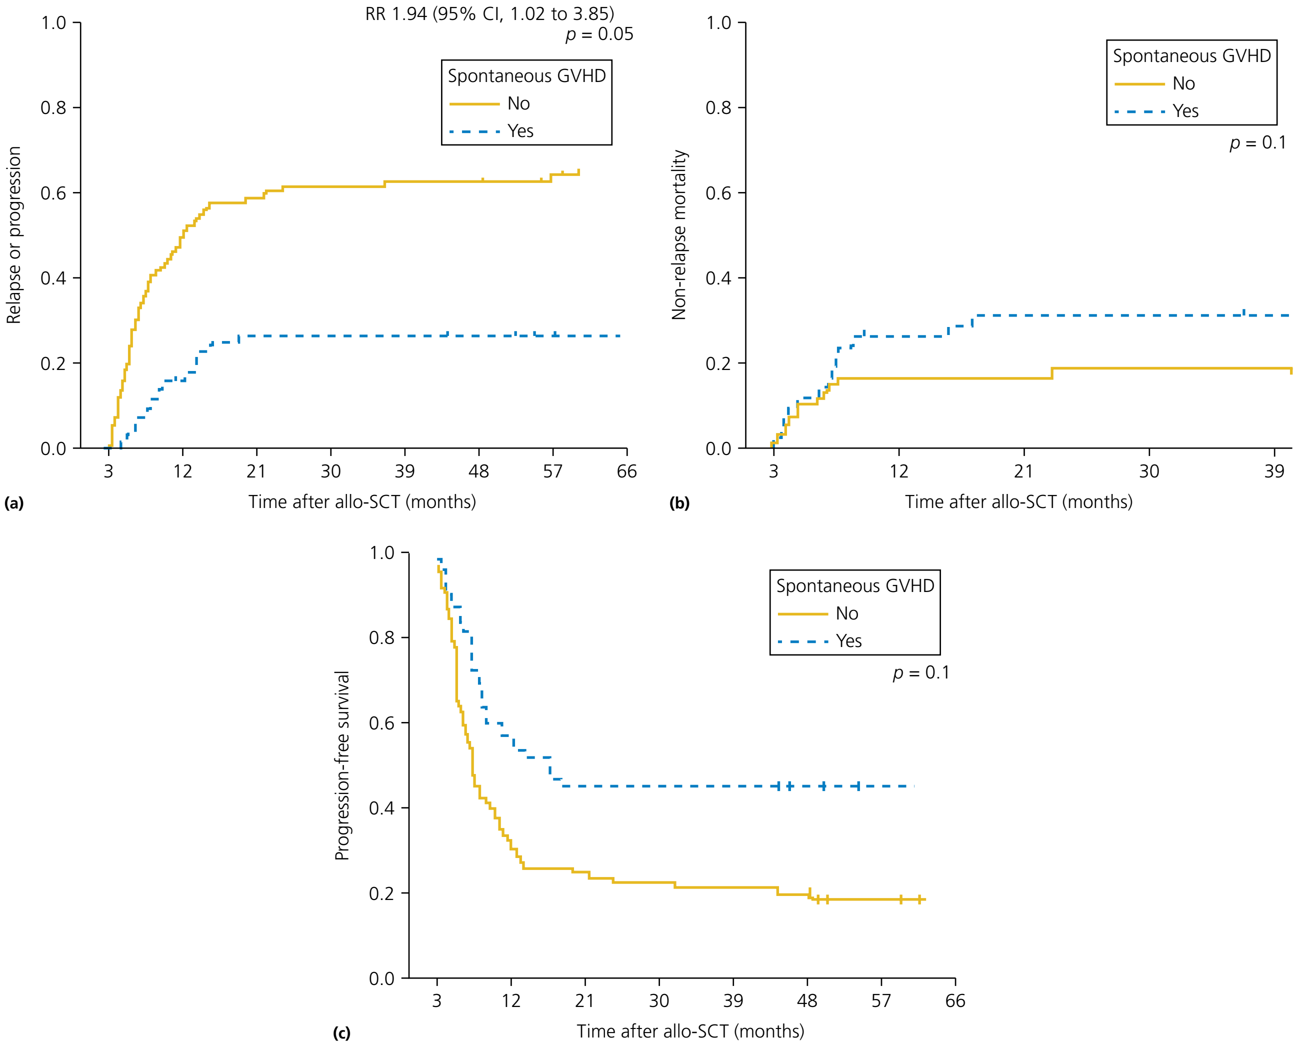

Figure 56.7 Influence of chronic graft-versus-host disease on the outcome after allogeneic hematopoietic cell transplantation. Cumulative incidence of (a) relapse or progression, (b) non-relapse mortality, and (c) Kaplan–Meier estimation of progression-free survival. Source: Sureda et al. 2008 [121]. Reproduced with permission of the American Society of Clinical Oncology.

of RIC allogeneic HCT was compared with the outcome of conventional non-transplant salvage therapy in 72 patients with HD relapsing following autograft [130]. Thirty-eight underwent alemtuzumab-containing RIC and 34 did not. The OS from both diagnosis and autograft was significantly better in the RIC allogeneic HCT group, with actuarial survival at 10 years from diagnosis of 48% compared with 15% ($p = 0.0001$) and survival at 5 years from autograft of 65% compared with 15% ($p \leq 0.0001$) These results support the use of RIC followed by allogeneic HCT in patients with relapsed HD following aHCT. Moreover, these studies confirm the existence of a GVHL effect associated with the development of chronic GVHD.

Results of allogeneic HCT for HD are displayed in Table 56.7. The results of allogeneic HCT for HD using RIC appear to be better than those reported with full-intensity myeloablative conditioning, especially in patients who have relapsed after a prior aHCT. This approach should be considered for patients who relapse after aHCT. As emerged from the above studies, chemosensitive disease and complete remission status at transplant are the most important factors to improve survival after allogeneic HCT. Alternative treatment strategies should be explored in patients with chemoresistant disease. Recent studies have shown that brentuximab vedotin [131] and bendamustine [98,99] can induce remission in patients with relapsed HD that enabled them to undergo allogeneic HCT. Additional studies are required to compare results with those of other approaches, determine the appropriate timing of transplantation, develop optimal RIC regimens, and design strategies to decrease toxicity and the risk of GVHD.

Other investigators have studied the strategy of aHCT followed by RIC allogeneic HCT for HD (see above). This approach is designed to exploit a GVHL effect in patients who have achieved a minimal disease state following an HDT regimen. Carella et al. demonstrated the feasibility of this approach [47]. Ten patients with relapsed and refractory HD received HDT followed by aHCT. At a median of 84 days after aHCT, patients underwent allogeneic HCT after conditioning with fludarabine and cyclophosphamide. Five patients were alive between 210 and 430 days after the second transplant. Additional studies are required to assess the curative potential of this approach.

Haploidentical related transplantation

To permit HLA-haploidentical HCT after non-myeloablative conditioning, investigators at Johns Hopkins University and the Fred Hutchinson Cancer Research Center incorporated high-dose post-transplantation cyclophosphamide to achieve the selective depletion of alloreactive T cells. Subsequently, immunosuppressive therapy with tacrolimus and mycophenolate mofetil was begun to control both rejection and GVHD. The outcomes of haploidentical related HCT ($n = 28$) were compared with those for HLA-matched related donor ($n = 38$) and unrelated donor ($n = 24$) HCT patients with relapsed or refractory HD who underwent non-myeloablative conditioning regimens [132]. Patients were heavily pretreated with a median of five regimens and 92% had failed aHCT and local radiation therapy (83%). There was no significant differences in OS between the three groups; however, there were significantly decreased risks of relapse for haploidentical related recipients compared with HLA-matched related ($p = 0.01$) and unrelated ($P = 0.03$) recipients. NRM was also significantly lower for haploidentical recipients than HLA-matched related recipients ($p = 0.02$). There were no differences in the incidences of severe grade III–IV acute or chronic GVHD between the groups. These results suggest that alternative donor sources are a viable option, particularly for those patients who may have a limited window of opportunity to proceed to allogeneic HCT.

Umbilical cord transplantation

The majority of candidates of allogeneic HCT will not have an HLA-matched sibling donor. Matched unrelated donors may be used, although many patients will not have suitable donors, and this option may be associated with a higher risk of GVHD and transplant-related mortality. The use of unrelated umbilical cord blood (UCB) has the advantages of rapid availability and lower risk of GVHD despite donor-recipient HLA disparity.

Investigators from Minnesota compared the results of RIC allogeneic HCT with UCB in 9 patients, with the results of transplantation in 12 patients with HLA-matched siblings [133]. The cumulative incidences of acute and chronic GVHD, as well as treatment-related mortality, were similar in both groups. The 2-year PFS

Table 56.7 Results of allogeneic hematopoietic cell transplantation for Hodgkin disease

Ref.	*n*	Regimen	Mortality	Outcome
[113]	100	Myeloablative	61% 3-yr TRM	15% 3-yr DFS
[113]	53	Myeloablative	43%	27% 10-yr EFS
[112]	45	Myeloablative	65% 4-yr TRM	15% 4-yr PFS

[126]	92	RIC (86% prior aHCT, 23 URD)	8% at 1 yr	48% 1-yr PFS
[127]	143	RIC (89% prior aHCT, 100 %URD)	15% at 2 yrs	30% 1-yr PFS

TRM, transplant-related mortality; DFS, disease-free survival; EFS, event-free survival; PFS, progression-free survival; RIC, reduced-intensity conditioning regimen; aHCT, autologous hematopoietic cell transplant; URD, unrelated donor; UCB, umbilical cord blood; MSD, matched sibling donor; OS, overall survival; mo, month; yr, year.

was estimated to be 25% following UCB allogeneic HCT, as compared with 20% for patients with matched sibling donors ($p = 0.67$). The actuarial 2-year PFS was 0% for patients with primary refractory disease, and those who relapsed within one year of aHCT. These results demonstrate that allogeneic HCT using UCB may be an alternative for patients without matched sibling donors or fully-matched unrelated donors.

High-dose therapy regimens

A wide variety of HDT regimens have been used with aHCT for HD (Table 56.8). No prospective trials have been performed, although regimens have been compared retrospectively. HDT regimens are frequently divided into those that use TBI and those that contain only drugs. Use of radiation with prior treatment often eliminates the possibility of using TBI.

Investigators in Seattle examined the influence of the preparative regimen in a cohort of HD patients who were treated with both autologous and allogeneic HCT [110]. No significant differences in EFS were observed when TBI-containing and drug-only regimens were compared, although 5-year OS rates were 28 and 14%, respectively ($p = 0.081$). The actuarial 5-year survival was 25% for patients who received cyclophosphamide and TBI compared with 11% for patients who received busulfan and cyclophosphamide ($p = 0.0610$). Patients treated with cyclophosphamide and TBI had similar outcomes to patients treated with cyclophosphamide, carmustine, and etoposide. A retrospective analysis of HD patients undergoing autologous or allogeneic HCT at Johns Hopkins University also failed to note differences in outcome when TBI-containing regimens were compared with regimens using chemotherapy alone [113]. Patients at City of Hope received a regimen of TBI, etoposide, and cyclophosphamide, or else carmustine, etoposide, and cyclophosphamide if they had received prior radiation [37]. No significant differences in response rate, DFS, OS, or toxicity were observed. At Stanford University, patients received TBI, etoposide, and cyclophosphamide, or regimens where carmustine or lomustine were substituted for TBI [21]. No significant differences in OS, freedom from progression, or EFS were noted. Similarly, there were no differences in outcome when TBI-containing regimens were compared with drug-only regimens in an ABMTR analysis [27]. An EBMT analysis also failed to show significant differences in PFS or OS associated with the use of TBI [55]. At MSKCC, there were no significant differences in EFS and OS when HD patients were treated with a regimen using accelerated fraction total lymphoid irradiation combined with cyclophosphamide and etoposide, compared with a high-dose chemotherapy regimen [20].

Table 56.8 Commonly used high-dose therapy regimens for Hodgkin disease

Regimen	Total dose administered
CBV	Cyclophosphamide, 4.5–7.2g/m^2 or 100mg/kg Carmustine, 300–600mg/m^2 or 15mg/kg Etoposide, 750–2400mg/m^2 or 60mg/kg
BEAC	Carmustine, 200–400/mg/m^2 Etoposide, 600–1200mg/m^2 Cytarabine, 800–1200mg/m^2 Cyclophosphamide, 140–180mg/kg or 6–7.5g/m^2
BEAM	Carmustine, 300–400mg/m^2 Etoposide, 400–1600mg/m^2 Cytarabine, 400–1600mg/m^2 Melphalan, 140mg/m^2
CY, TBI	Cyclophosphamide, 120–200mg/kg Total body irradiation, 800–1320cGy
VP-16, CY, TBI	Etoposide, 30–60mg/kg Cyclophosphamide, 60–120mg/kg Total body irradiation, 1200–1375cGy
BU, CY	Busulfan 16mg/kg Cyclophosphamide 120–200mg/kg

The use of TBI may be associated with increased pulmonary toxicity, particularly in patients who have received prior mediastinal irradiation. Spanish registry results showed that the use of TBI-containing regimens prior to aHCT for HD was associated with a significantly higher risk of early transplant-related mortality (relative risk 2.3, $p = 0.02$) [9]. A multivariate analysis of another Spanish registry study of aHCT for HD identified the use of TBI-containing regimens to be associated with a 6.09-fold risk of NRM ($p = 0.0001$) [64]. The actuarial 5-year OS was 33% for patients transplanted with TBI-containing regimens compared with 60% for those transplanted with chemotherapy regimens ($p = 0.01$), although this difference was not significant on multivariate analysis.

One of the most common high-dose chemotherapy regimens used prior to aHCT for HD is the CBV [cyclophosphamide, BCNU (carmustine), etoposide] regimen developed at the M.D. Anderson Cancer Center. The original CBV regimen has been modified and individual institutions have used widely differing schedules (Table 56.8). No prospective trials have examined whether variations in the CBV regimen lead to different outcomes, although higher doses of carmustine have been associated with an increased risk of pulmonary toxicity, particularly in patients who have received prior chest irradiation [110,134]. The addition of cisplatin to the CBV regimen did not result in significant differences in outcome, although this modification allowed the dose of carmustine to be reduced [36,135]. Another high-dose chemotherapy regimen for HD aHCT is the BEAM regimen, which was developed by investigators in London and has also been widely modified (Table 56.8) [66]. Retrospective analyses have failed to show significant differences in survival when CBV-type regimens and BEAM-type regimens were compared [25,65]. In one retrospective comparison, CBV was associated with significantly higher rates of transplant-related morbidity and mortality, although an unusually high dose of carmustine (800mg/m^2) was used [136]. In one study, escalation of the total dose of etoposide in the BEAM regimen to 1600mg/m^2 did not significantly improve survival [137].

A variety of other HDT regimens have also been used prior to aHCT for HD. In Seattle, a retrospective analysis compared results of a regimen containing busulfan, melphalan, and thioTEPA with results from the combination of etoposide, cyclophosphamide, and TBI for patients undergoing aHCT for HD [39]. No significant differences in toxicity, EFS, or OS were observed. Other HDT regimens used prior to aHCT for HD include busulfan, etoposide, and cyclophosphamide [30], carmustine, etoposide, and cisplatin [138], thioTEPA, mitoxantrone, and carboplatin [139], and high-dose sequential chemotherapy regimens [40].

It is unclear from existing data whether any HDT regimen is superior for patients with HD. Prospective trials will be required to prove the superiority of any regimen and it is difficult to recommend any single regimen, although TBI and higher doses of carmustine should be avoided in patients with pulmonary disease or a history of chest irradiation.

Several institutions have tested the use of double (tandem) aHCT for HD (see earlier). This approach is feasible and good outcomes are possible, although a significant proportion of patients are not able to receive the second planned transplants [45,46].

Summary and future directions

Over the last 25 years, the use of HDT followed by autologous HCT has become the treatment of choice for most patients with relapsed and refractory HD. The outcomes are better in chemotherapy-sensitive patients and those with good prognostic factors at relapse. New approaches are needed for patients with primary refractory HD, since the chance of long-term remission remains poor even with autologous HCT. Novel approaches using brentuximab vedotin as salvage therapy before transplant are being explored. Long-term survivors of autologous HCT for HD are at higher risk of NRM due to prior exposure to multiple chemotherapies and radiotherapy. New strategies to reduce long-term complications are needed. Incorporation of early interim FDG-PET and at completion of therapy may help identify patients who may not be curable with conventional therapy and thus benefit from early transplant. Despite the lower incidence of NRM, the role of reduced-intensity allogeneic HCT for relapsed and refractory HD requires further studies. At present, patients with chemosensitivity benefit from allogeneic HCT and the existence of a GVHL effect has been clearly demonstrated. The optimal choices of RIC regimens, the best GVHD prophylaxis, the type of hematopoietic stem cell, and the role of DLI require further studies. Nevertheless, allogeneic HCT should be considered in selected patients with HD who relapsed after autologous HCT.

CHAPTER 57

Hematopoietic Cell Transplantation for Non-Hodgkin Lymphoma (B Cell)

Leslie L. Popplewell[1] **and Ginna G. Laport**[2]

[1] City of Hope Medical Center, Duarte, CA, USA
[2] Stanford University Medical Center, Stanford, CA, USA

Introduction

Non-Hodgkin lymphomas (NHLs) are a diverse group of malignant neoplasms derived from either B-cell progenitors, T-cell progenitors, mature B cells, or mature T cells. It was estimated that approximately 72,000 men and women would be diagnosed with NHL and 20,000 men and women would die of lymphoma in 2015 [1]. Since hematopoietic cell transplantation (HCT) is recognized as a potentially curative treatment for NHL, the use of HCT in the treatment of patients with NHL has risen steadily. In 2009, over 3500 HCTs were performed in the United States for treatment of NHL, of which over 2500 were autologous HCT (autoHCT) [2]. This chapter reviews the use of autoHCT and allogeneic HCT (alloHCT) for B-cell NHL. HCT for T-cell NHL is discussed in Chapter 58. Readers are referred to other chapters for complete and related discussions of preparative regimens (Chapters 20 and 21), radioimmunotherapy (Chapter 23), minimal residual disease (Chapter 25), hematopoietic cell sources (Chapter 4), complications after HCT (chapters in Section 7) and adoptive immunotherapy (Chapter 69).

Diffuse large B-cell lymphoma

Diffuse large B-cell lymphoma (DLBCL) is the most common subtype of NHL and accounts for approximately 30% of NHLs diagnosed each year with the median age at diagnosis being 64 years [3]. The addition of the anti-CD20 monoclonal antibody rituximab (RTX) to CHOP [cyclophosphamide, hydoxydaunomycin (doxorubicin), vincristine (Oncovin), prednisone] has significantly improved outcomes for DLBCL patients. The International Prognostic Index (IPI), developed in 1993, is used for risk stratification for patients with DLBCL, and the age-adjusted IPI (aaIPI) is also widely applied particularly to tailor more intensive therapy such as autoHCT [4]. The risk factors included in the IPI include age, performance status, lactate dehydrogenase level, multiple extranodal sites of involvement, and stage of disease. The number of risk factors present at diagnosis segregates patients into low-, intermediate-, and high-risk groups. Patients treated with CHOP or CHOP-like regimens have predicted 5-year survival rates ranging from 73% in the low-risk group to 26% in the high-risk group, with an increased risk of death due to both a lower complete remission (CR) rate and a higher rate of relapse from CR. However, over 50% of patients who achieve a CR will relapse within 2–3 years and autoHCT is the standard of care for patients who can demonstrate chemosensitive disease with salvage therapies. AutoHCT can also salvage a subset of patients who are induction failures to front-line chemoimmunotherapy. AlloHCT is typically reserved for patients who are not candidates for autoHCT, such as those with marrow involvement, patients with very high-risk features such as the "double hit" lymphomas, and those who have relapsed after autoHCT.

Autologous HCT

Several phase II trials demonstrated survival advantages for autoHCT as upfront therapy in high-risk patients, which led to randomized trials of autoHCT as consolidation therapy for aggressive lymphomas [5]. A meta-analysis with 11 trials with over 2000 patients who received autoHCT as consolidation demonstrated comparable mortality in both HCT and control arms; however, significant heterogeneity was noted among the trials with regard to trial design. No overall survival (OS) benefit was noted [6]. Many of the original studies examining the efficacy of autoHCT for relapsed or refractory DLBCL were conducted prior to the addition of RTX to CHOP. In the "post-RTX age," response rates and both OS and progression-free survival (PFS) were improved after conventional chemotherapy and remain superior at 10 years of follow-up. Hence justification of upfront autoHCT for high-risk presentation DLBCL requires a more stringent risk-to-benefit ratio [7]. A position statement from the American Society for Blood and Marrow Transplantation in 2011 concluded that autoHCT as first-line therapy is not recommended for any risk group of the IPI at that time; however, none of the published studies included RTX in their treatment protocols, and ongoing studies that include RTX may change this recommendation [5].

In the RTX era, two randomized studies have been conducted testing the role of autoHCT in the front-line therapy of unfavorable (high- and high–intermediate-risk patients) DLBCL. A Southwest Oncology Group study used either CHOP or R-CHOP (CHOP with rituximab added) induction therapy followed by either additional cycles of R-CHOP or autoHCT [8]. There was a significant difference in 2-year PFS between the autoHCT arm and the standard arm, 69% versus 56%, respectively ($p = 0.005$), but for OS the differences were not significant, 74% versus 71% ($p = 0.32$). By exploratory analyses, when the high–intermediate IPI and high IPI groups were analyzed separately, the high IPI patients who received HCT had a stronger improvement in 2-year PFS and OS compared with

the standard arms (PFS 75% vs. 41%; OS 82% vs. 64%). The trial was not powered to detect differences between these subsets. No difference was seen between treatment effects according to induction therapy or between B-cell and T-cell histology.

The Italian Lymphoma Foundation conducted an upfront HCT trial as a multicenter randomized trial with a 2 × 2 factorial design for high-risk (aaIPI 2 or 3) patients [9]. Patients were first randomized to either of one of two RTX dose-dense treatments (RCHOEP14 vs. RmegaCHOP) and responding patients then underwent a second randomization to either HCT or observation. The primary end-point was event-free survival (EFS), and all analyses were performed with an intent-to-treat analysis. The 2-year PFS was 72% in the HCT arm versus 59% in the no-HCT arm ($p = 0.008$), with no difference seen in OS.

For DLBCL patients receiving front-line chemotherapy, the use of interim [^{18}F]fluorodeoxyglucose positive emission tomography (FDG-PET) scanning after 2–4 cycles of chemotherapy has demonstrated prognostic significance. Patients with a positive interim FDG-PET scan after two cycles of CHOP or R-CHOP were correlated with a poorer outcome in a study by Haioun et al. [10]. Additional cycles of the same chemotherapy were not sufficient to cure these patients. Upfront autoHCT has been offered to DLBCL patients in the context of interim FDG-PET scanning during induction chemotherapy. Investigators at the Memorial Sloan Kettering Cancer Center prospectively studied interim FDG-positive disease using a risk-adapted strategy in 98 patients with DLBCL treated with four cycles of R-CHOP14 [11]. After four cycles, a PET scan was performed and patients with FDG-negative scans received ICE (ifosfamide, carboplatin, etoposide) for three cycles followed by observation. Patients with a positive interim PET scan were biopsied and, if positive for residual NHL on biopsy, received ICE followed by autoHCT. Of the 38 patients with a positive interim scan, only five had a positive biopsy and received autoHCT. Three of these five patients remained alive and free of disease, and all 33 patients with positive interim PET scans and negative biopsies received ICE without autoHCT. Twenty-six of these 33 patients remained alive and without subsequent relapse. This is a cautionary note for investigators considering the use of an interim PET scan as an indication for autoHCT.

Autologous HCT for DLBCL – relapsed disease

Patients who relapse after primary therapy, or who fail to achieve CR with primary treatment, should be considered for autoHCT. The PARMA trial was a randomized, multicenter trial that compared autoHCT with consolidation therapy in 215 patients with chemotherapy-sensitive NHL [12]. All patients had achieved a first remission with an anthracycline-containing chemotherapy regimen. All patients received DHAP (dexamethasone, high-dose cytarabine, cisplatin) with harvesting of autologous bone marrow, followed by a second cycle of DHAP. Patients were then randomized to four more cycles of DHAP versus autoHCT. There were no differences in prognostic factors between the groups. After a median follow-up of 63 months, the response rate was 84% after HCT versus 44% after conventional therapy. At five years, EFS was 46% in the HCT group and 12% in the group receiving chemotherapy only ($p = 0.001$) The OS was 53 and 32%, respectively ($p = 0.038$). Subsequent results from the PARMA study indicated that patients with a longer initial remission (relapse after >1 year vs. <1 year) had a higher response to DHAP (69% vs. 40%) and superior OS at 8 years (29% vs. 13%). Survival advantages were only seen in patients with an IPI of >0 at the time of relapse [13].

The addition of rituximab to front-line chemotherapy has allowed more patients to achieve and maintain remission. However, increasing evidence has shown that patients who had received RTX prior to salvage therapy and autoHCT fared significantly worse than patients who were RTX-naïve prior to relapse and subsequent autoHCT. In a retrospective analysis, Spanish investigators from the Grupo Español de Linfomas/Trasplante Autólogo de Médula Ósea (GEL/TAMO) evaluated the influence of prior RTX use in 163 patients with relapsed or refractory DLBCL who received R-ESHAP (rituximab plus etoposide, cytarabine, cisplatin, methylprednisolone) salvage chemotherapy followed by autoHCT. Sixty-nine patients had not received RTX prior to relapse. The response to salvage therapy and also PFS and OS were significantly worse in the patients who had received RTX as part of front-line therapy. With a median follow-up of 29 months, the PFS for the RTX-exposed group versus the RTX-naïve group was 17% versus 57% ($p < 0.0001$) and the OS was 38% versus 67% ($p = 0.0005$) [14].

This observation was confirmed in the Collaborative Trial in Relapsed Aggressive Lymphoma (CORAL), which was a European intergroup prospective phase III study that enrolled 396 patients with DLBCL in first relapse or with primary refractory disease. Patients were randomized to salvage chemotherapy with R-ICE (rituximab, Ifosfamide, carboplatin, etoposide) or R-DHAP (rituximab, dexamethasone, high-dose cytarabine, cisplatin) [15]. Responding patients proceeded to autoHCT and underwent a second randomization after HCT to either observation or RTX maintenance for 1 year. A total of 244 patients (63%) had received RTX as part of first-line therapy. On comparing the R-ICE and R-DHAP arms, there was no difference in response rates, 63.5% versus 62.8%, respectively or in EFS, 26% versus 35%, respectively. The factors that significantly affected response to salvage and EFS were refractory/relapse <12 months from diagnosis, secondary aaIPI >1 and prior exposure to RTX. The group of patients who relapsed <12 months from diagnosis and had prior RTX exposure had an inferior PFS compared with early relapsed patients without prior RTX exposure (Figure 57.1a). For patients who relapsed >12 months from diagnosis, prior RTX exposure did not affect PFS.

Regarding the impact of maintenance RTX after HCT, no differences in EFS, PFS, or OS were seen in the maintenance versus observation arm. The 4-year post-HCT EFS was 52% in the maintenance arm versus 53% in the observation group ($p = 0.7$). More adverse events after day 100 were reported in the maintenance arm, the majority of which were infections. The secondary aaIPI was highly significant ($p < 0.001$) for EFS, PFS, and OS (Figure 57.1b). A striking observation was the significant difference in PFS between males and females at the time of second random assignment and after maintenance therapy. The females had a superior EFS at both time points, attributed to the higher RTX clearance in males resulting in lower RTX exposure. The EFSs for males and females were 43% and 69%, respectively. In the Cox model for maintenance therapy, the secondary aaIPI ($p < 0.001$) and male gender ($p = 0.01$) were significant prognostic factors [16].

The CORAL investigators retrospectively evaluated the prognostic value of the molecular subtype or cell of origin in the relapsed/refractory DLBCL patients [17]. Based on the availability of histologic material, tumor biopsies of 232 patients were analyzed by immunohistochemistry for CD10, *bcl-6*, MUM1, and FOXP1 and by fluorescence in situ hybridization (FISH) for *bcl-2*, *bcl-6*, and *c-MYC* breakpoints. On the basis of the Hans algorithm, which utilizes immunohistochemistry to segregate patients into germinal center B-cell-like (GCB) and activated B-cell-like (ABC)

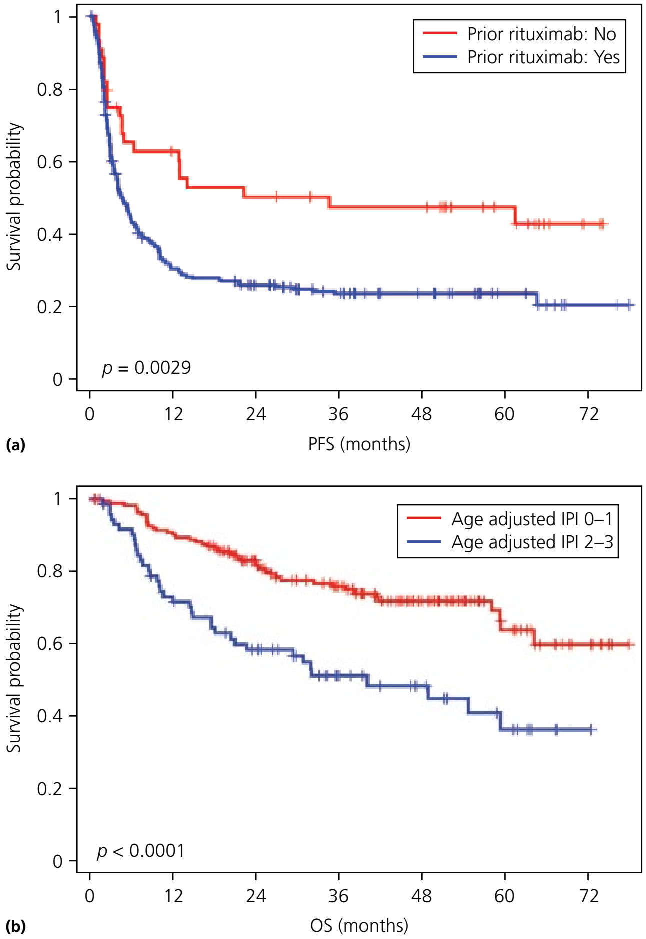

Figure 57.1 (a) Progression-free survival from diagnosis by prior rituximab therapy in diffuse large B-cell lymphoma. Failure from diagnosis was <12 months. CORAL study. (b) Overall survival according to the age-adjusted International Prognostic Index at the time of relapse in diffuse large B-cell lymphoma. CORAL Study. Source: Gisselbracht et al 2010 [15]. Reproduced with permission of the American Society of Clinical Oncology.

subtypes, 46% of the patients were classified as "GCB-like" and 49% as "ABC-like" [18]. The GCB-like patients had a significantly better PFS and OS compared with the ABC-like patients, with PFS of 70% versus 28% and OS of 74% versus 40%, respectively. When response to salvage was analyzed by cell of origin and by salvage regimen, the GCB-like patients treated with R-DHAP had a 100% 3-year PFS whereas the 3-year PFS for the GCB-like patients treated with R-ICE was only 27%. The ABC-like DLBCL patients had an unfavorable outcome irrespective of the salvage regimen. Hence prospective randomized trials with cell of origin stratification are needed to evaluate survival benefit with R-DHAP over R-ICE in patients with GCB-like DLBCL.

The role of radioimmunotherapy (RIT) in HCT is covered comprehensively in a separate chapter (Chapter 23) but selected trials are worth mentioning here. Radioisotope-labeled monoclonal antibodies deliver targeted radiation to malignant cells expressing a specific antigen with the added benefit of irradiating neighboring malignant cells with lower or absent antigen expression. RIT is an ideal agent to incorporate into HCT preparative regimens for B-cell NHL. Myelosuppression, the major adverse effect of RIT, can be overcome by infusion of hematopoietic stem cells. Several phase I and II trials have demonstrated the feasibility and safety of adding standard dose or escalating doses of RIT to the HCT preparative regimen using anti-CD20 RIT with [^{90}Y]ibritumomab tiuxetan or [^{131}I]tositumomab [19–21].

A multicenter phase III trial, conducted by the Blood and Marrow Transplant Clinical Trials Network (BMT CTN) randomized chemosensitive persistent or relapsed DLBCL patients to autoHCT with either the rituximab plus BEAM [BCNU (carmustine), etoposide, cytosine arabinoside, melphalan] preparative regimen (n = 113) or BEAM plus [^{131}I]tositumomab (n = 111). There was no significant difference in 2-year PFS (48.6% vs. 47.9%, p = 0.97) and 2-year OS (66% vs. 61%, p = 0.38). The treatment-related mortality (TRM) was also comparable (4.1% vs. 4.9%, p = 0.97), although the RIT arm had a significantly higher mucositis score [22]. There is an ongoing multicenter phase III trial with a similar trial design to the previously mentioned BMT CTN trial that is testing the efficacy of [^{90}Y]ibritumomab tiuxetan with BEAM. Patients with relapsed or persistent DLBCL are randomized to autoHCT with a conditioning regimen of BEAM versus BEAM + [^{90}Y]ibritumomab tiuxetan. It also should be noted that the most promising outcomes in the phase I and II studies incorporating RIT preparative regimens used higher doses of RIT and further study is perhaps necessary with such doses.

Allogeneic HCT for DLBCL

AlloHCT for relapsed DLBCL has lower rates of relapse than autoHCT but at the expense of higher treatment-related morbidity and mortality. The earliest retrospective studies of alloHCT in NHL lent support to the existence of a graft-versus-lymphoma (GVL) effect [23]. This is demonstrated by lymphoma regression after withdrawal of immunosuppression or after infusion of donor lymphocytes.

This finding of lower relapse with alloHCT was also observed in a large European Group for Blood and Marrow Transplantation (EBMT) Registry study, which analyzed 1185 lymphoma patients transplanted between 1982 and 1998, and compared the results with those of approximately 14,000 autologous procedures during the same period [24]. In a matched analysis, for patients with intermediate-grade NHL, the relapse rates for allogeneic and autologous recipients were approximately 35 and 60%, respectively. However, there was no difference in OS due to the significantly higher TRM seen in the allogeneic group. A registry study by the Center for International Blood and Marrow Transplant Research (CIBMTR) compared outcomes of 916 DLBCL patients undergoing first autoHCT (n = 837) or myeloablative alloHCT (n = 79) [25]. Allogeneic recipients were more likely to have advanced disease, more prior chemotherapy regimens, and resistant disease. With a median follow-up of 60 months for the autologous patients versus 81 months for the allogeneic patients, alloHCT was associated with a higher 1-year TRM [relative risk (RR) 4.88], treatment failure (RR 2.06), and mortality (RR 2.75). The risk of disease progression was similar in both groups. The disparity in risk features may explain the absence of an observed GVL effect.

For most DLBCL patients, alloHCT is more often utilized after failure of prior autoHCT. Three retrospective trials analyses reported a PFS ranging from 35 to 49% and OS ranging from 45 to 59% in DLBCL patients who received fludarabine-based reduced-intensity conditioning (RIC) regimens (Table 57.1). Over 70% of patients in all three studies had failed a prior autoHCT. Two large registry studies in Europe reported the outcomes of DLBCL patients

Table 57.1 Reduced intensity alloHCT for relapsed diffuse large B-cell lymphoma

after RIC or ablative alloHCT and included only patients who had relapsed after autoHCT. The long-term survival approached 30–40% with a non-relapse mortality (NRM) of 28% in both studies [26,27]. The most important prognostic factor was disease status at the time of alloHCT and not the intensity of the conditioning regimen. An analysis was conducted of 147 patients with hematologic malignancies who relapsed after autologous (n = 135), allogeneic (n = 10), or syngeneic (n = 2) HCT and then were subsequently treated with human lymphocyte antigen (HLA)-matched related or unrelated grafts after non-myeloablative conditioning with 2Gy of total body irradiation (TBI) with or without fludarabine [28]. The best outcomes were observed in patients with NHL (24 aggressive NHL, 12 indolent, and 14 mantle cell lymphoma), as compared with myeloma or classical Hodgkin lymphoma patients. Being in a partial remission (PR) or CR at the time of alloHCT and developing chronic graft-versus-host disease (GVHD) were associated with a lower risk or progression or relapse. Factors associated with a better OS were remission status, lack of comorbidities, and absence of acute GVHD. Other groups have identified increased NRM in patients who were older, or whose initial remission after autoHCT was less than 12 months [27].

Double hit lymphoma

It is now recognized that DLBCL with concurrent abnormalities including the *MYC* gene rearrangement and the t(14;18) (*c-myc*$^+$/*bcl-2*$^+$) constitute a subtype commonly referred to as “double hit (DH) lymphoma” with particularly poor clinical outcomes, even with intensive upfront therapy [29]. The double hit subtype has been observed in 2–11% of newly diagnosed DLBCL patients. Evaluation with FISH for *MYC* should be performed for NHL patients with a mature B-cell phenotype who are CD10 positive and either *bcl-6* or *bcl-2* positive. This is especially relevant if a diffuse pattern with or without a “starry sky pattern” is seen, and in the entity B-cell lymphoma, “unclassifiable, intermediate between DLBCL and BL (U-DLBCL/BL)”.

The standard of care for newly diagnosed double hit DLBCL patients has not been established [30]. Most DH NHL patients present with high IPI scores and with bone marrow and central nervous system (CNS) frequently involved. A review of published clinical studies in which DH lymphomas were separately analyzed demonstrated a variety of approaches, including doxorubicin-based chemotherapy regimens and autoHCT with a median OS of only 0.2–1.5 years [31–35]. In a recent study with 303 patients with DLBCL treated with R-CHOP, 35 patients had a MYC rearrangement, of which 27 were DH cases [36]. All *MYC* cases had an inferior outcome. All four patients with DLBCL with a DH and who received ifosfamide-based high-intensity regimens died within 5 months after the start of treatment. The poor prognosis of these patients led some centers to advocate the use of autoHCT or alloHCT in the upfront setting for patients. However, given the lack of published literature for this approach, its merits are unclear. In one retrospective study of 16 patients, the DH patients treated with autoHCT or alloHCT as part of front-line therapy still had a poor median survival of less than 6 months [31].

HCT for double hit lymphoma – relapsed disease

Although standard of care for patients with relapsed DLBCL includes salvage chemotherapy followed by autoHCT, recent studies by Cuccuini et al. indicated that *MYC*-positive DLBCL is not salvaged by classical R-ICE or R-DHAP followed by autoHCT [37]. Of the 477 patients in the previously mentioned CORAL study, 28 patients (17%) were confirmed to have a *MYC* rearrangement. Twenty-one of these patients had one or more concurrent translocations, including either *bcl-2* and, in some cases, also *bcl-6*. Patients with the DH markers had a 4 year PFS and OS much lower than those of patients in the *MYC*-negative category (18% vs. 42% and 29% vs. 62%, respectively). Type of salvage (R-ICE vs. R-DHAP) had no impact on survival. These findings suggest that novel therapies and possibly alloHCT should be considered in such patients. However, it is not clear if even these approaches will improve survival.

Mantle cell lymphoma

Mantle cell lymphoma (MCL) is a B-cell neoplasm comprising 3–10% of all NHLs. It occurs in middle-aged to older individuals with a median age of 50 years and a male predominance. In addition to lymph nodes, other sites commonly involved include spleen, bone marrow, peripheral blood, gastrointestinal tract, and Waldeyer’s ring. Most patients present with stage III or IV disease. Although some MCL patients can be followed without aggressive treatment at the time of diagnosis, most require multi-agent chemotherapy. There is currently no standard therapy for newly diagnosed or relapsed disease, but autoHCT is often offered as part of front-line therapy. Early treatment with CHOP chemotherapy resulted in low CR rates of 25% or less with patients relapsing after a median of only 1–2 years [38–41]. The use of RTX in the upfront setting improved outcomes, with R-CHOP yielding a CR rate of 35%. A recent study added bortezomib to R-CHOP and increased the CR rate to 64% [42]. The R-hyperCVAD (RTX, vincristine, doxorubicin, dexamethasone) regimen has gained widespread use following demonstration of CR rates as high as 90% in the front-line setting with a prolonged 5-year failure-free survival (FFS) of 60% in younger patients [43]. A risk-adapted approach at the M.D. Anderson Cancer Center demonstrated that as treatments changed over the years, the best improvements were seen with the additional RTX and the combination of R-hyperCVAD [44].

The IPI developed for DLBCL has been applied to MCL but is less predictive of survival compared with the Mantle Cell Prognostic Index (MIPI) [4,45]. The outcome of patients with MCL varies from a median OS of 60% at 5 years for the low-risk group to only 29 months for the high-risk group. The MIPI appears to assist with prediction of survival both at the time of initial diagnosis and after autologous transplantation. Budde et al. reported that the MIPI was independently associated with survival after HCT in patients who underwent autoHCT as initial consolidation [46]. For patients with low-, intermediate-, and high-risk MIPI, the OS at 2.5 years after HCT was 93, 60, and 32%, respectively. After adjustment for the MIPI, an intensive induction regimen was not associated with improved survival after HCT in all patients.

Front-line application of Autologous HCT

AutoHCT has yielded disappointing results in relapsed MCL patients, which led to consideration of autoHCT during CR1. A key trial was a prospective study conducted by the European Mantle Cell Consortium of 122 patients with advanced-stage MCL. Patients were randomly assigned to either high-dose cyclophosphamide and autoHCT or maintenance therapy with interferon-α after CHOP-like therapy. The results showed a significantly longer PFS in the autoHCT arm, 39 months versus 17 months ($p = 0.01$) for the interferon patients. No significant difference in OS was observed, 83% versus 77% ($p = 0.18$) for the autologous and interferon arms, respectively. However, the crossover design of the trial may have interfered with obtaining a meaningful OS end-point [41].

The Nordic group has extensively studied the role of autoHCT in CR1. The MCL-2 Nordic trial incorporated R-CHOP with higher doses of cyclophosphamide and doxorubicin alternating with high-dose cytarabine and consolidation with autoHCT using RTX in vivo-purged autoHCT [47]. The overall response and CR rate achieved were 96 and 54%, respectively. No relapses were reported after 5 years with the longest follow-up at 7.5 years, suggesting that some long-term remissions could be obtained. In the intent-to-treat analysis, the 10-year OS and EFS for all 160 patients was 58 and 43%, respectively [48]. The median OS was >10 years and the EFS was 7.4 years. The Ki-67 proliferation rate was the sole independent predictor of EFS. Compared with the Nordic MCL-1 trial, which had a similar trial design but did not use RTX or high-dose cytarabine, the MCL-2 trial demonstrated a higher molecular remission rate and improved EFS and OS compared with the historical controls from the MCL-1 trial [47,49] (Figure 57.2).

The ability of high-dose cytarabine and rituximab to increase CR rates and improve outcomes has been studied in several other prospective trials [50–52] (Table 57.2). A notable trial was reported by the GELA group in which cisplatin was incorporated in the induction regimen for 60 newly diagnosed MCL patients. Patients received R-CHOP followed by R-DHAP and responding patients proceeded to autoHCT. Either BEAM or a TBI-based regimen with cytarabine was given as a preparative regimen. The median EFS was 84 months and the OS was not reached with a follow-up of 67 months. No toxic deaths were reported [51].

At least two clinical trials have demonstrated rationale for administering maintenance RTX after autoHCT for MCL. Brugger et al. performed a prospective, multicenter phase II study of 31 patients, including 10 MCL cases, using a single course of RTX weekly for 4 weeks, beginning approximately 8 weeks after autoHCT [53]. Patients were monitored with polymerase chain reaction (PCR) for minimal residual disease. RTX consolidation post-HCT was tolerable, with the most common toxicity being non-life-threatening infection. At a median follow-up of 42 months (range 13–96 months) after HCT, the actuarial EFS was 81% at 4 and 5 years. PCR negativity was observed in 22% of the patients before HCT, 53% post-HCT ($p = 0.0547$), 72% after RTX maintenance ($p = 0.0018$), and 100% at 6 months post-HCT.

In the previously mentioned Nordic MCL-2 trial, the use of preemptive treatment with RTX after autoHCT was also studied

[54]. Twenty-six patients with evidence of molecular relapse after successful autoHCT (as evidenced by rising PCR levels of bcl-1/IgH (immunoglobulin H) and clonal IgH rearrangements in blood and marrow following HCT), were offered preemptive RTX 375mg/m^2 weekly for 4 weeks. A total of 92% of these patients were able to achieve molecular remission after "preemptive treatment." Median molecular and clinical relapse-free survival after preemptive treatment were 1.5 and 3.7 years, respectively.

The 2013 European Society for Medical Oncology consensus guidelines for MCL recommend that autoHCT should be incorporated into first-line therapy. No conditioning regimen has shown a clear superiority; however, TBI may improve PFS in patients in PR after induction [55].

Autologous transplant for relapsed disease

AutoHCT for MCL has been offered to patients beyond CR1 but high relapse rates remain problematic. The CIBMTR reported the outcomes of 151 MCL patients with relapsed disease who underwent autoHCT [56]. The 5-year OS was 40%, with 50% of patients eventually showing progressive disease. owing to these disappointing results, intensified conditioning regimens have been explored. A compilation of both EBMT and CIBMTR data on MCL patients receiving autoHCT between 1988 and 1998 resulted in a cohort of 195 patients with a median follow-up of 4 years. The 2- and 5-year OS were 76 and 50% and the PFS were 55 and 33%, respectively. Disease status at transplant was the most significant factor affecting survival: patients with chemosensitive disease but not in first CR were 2.99 times [95% confidence interval (CI) 1·66–5·38, $p < 0{\cdot}001$] more likely to die than patients transplanted in CR1.

Allogeneic HCT

Long-term DFS and cures have been reported in MCL patients after alloHCT, including patients who had failed a prior autoHCT. A retrospective analysis of 70 consecutive patients with refractory or relapsed MCL from 12 centers treated with RIC alloHCT was reported [57]. Forty-seven of the patients had previously been treated with autoHCT with the median number of prior therapies being two and median time from diagnosis to RIC alloHCT of 44 months. The 2-year EFS, OS, and TRM rates were 50, 53, and 32%, respectively. No difference in outcome was seen based on number of prior lines of therapy, but disease status at the time of RIC alloHCT reached statistical significance with regard to EFS. The EFS for CR patients was 62.5%, for PR patients 53%, and for patients with stable disease or progressive disease (PD) only 11%. The 3-year EFS for patients who had received a prior autoHCT was 49%.

A risk-adapted strategy for transplant for MCL was described by the group at the M.D. Anderson Cancer Center [44]. When RIC alloHCT was compared retrospectively with autoHCT, either in CR1 (AUTO1) or in the relapsed setting (AUTO2), the 6-year actuarial PFS for the allogeneic patients was 46% versus 39% for AUTO1 and 10% for AUTO2 patients. The respective actuarial 6-year OS were 53, 61, and 35%, respectively. These results showed that long-term DFS can be obtained in patients undergoing autoHCT in CR1 with an RTX-containing regimen or in patients with relapsed or refractory disease with RIC alloHCT.

A recent retrospective report from the CIBMTR demonstrated that alloHCT can salvage some patients with chemorefractory disease [58]. A total of 202 patients with refractory MCL were treated with either myeloablative (MA) or RIC conditioning; 33% of the RIC group and 13% of the MA group had had a prior autoHCT. At 3 years post-HCT, no significant differences were seen between the groups in NRM (47% MA vs. 43% RIC), relapse/progression (33% vs. 32%), PFS (20% vs. 25%), or OS (25% vs. 30%). Receipt of a bone marrow or T-cell-depleted allograft was associated with an increased risk of NRM and inferior PFS and OS.

Follicular lymphoma

Follicular lymphoma (FL) comprises 20% of all NHLs and is the second most common type of NHL diagnosed in the United States. The incidence increases with age with a median age at diagnosis of 60 years. FL cells are characterized by the cell surface markers CD19, CD20, and CD10 and express surface immunoglobulin. The t(14;18) translocation, which involves the *IgH*/*bcl-2* genes, occurs in up to 90% of follicular lymphomas and is also found in 20–30% of DLBCL patients [59]. The median survival of patients with FL ranges from 8 to 12 years but there is wide variability as some patients do not require treatment for many years whereas 15% of patients die within 2 years of diagnosis due to progressive or transformed disease [60]. FL remains incurable with standard therapy but the "watch and wait" approach remains acceptable in patients without bulky disease and who are asymptomatic. For patients who require treatment, treatment options include radiotherapy, chemotherapy, monoclonal antibody therapy, radioimmunoconjugates, and HCT. There is no consensus as to the optimal first-line or salvage therapeutic regimen but HCT should be considered for patients beyond first remission.

Autologous HCT for follicular lymphoma

First remission

The role of autoHCT as consolidation therapy for front-line treatment of FL patients has been explored in three large randomized trials in Europe [61–63]. In all three trials, patients with newly diagnosed FL received upfront combination chemotherapy and were then randomized to interferon maintenance therapy versus autoHCT. There was no difference in OS between the conventional chemotherapy arms and the autoHCT arms in all three trials, although a superior PFS was seen in the patients who underwent autoHCT in two of the trials. It should be noted that these trials were completed before RTX was routinely incorporated into front-line therapy.

A disturbing finding was the higher incidence of therapy-related neoplasms in the patients who received HCT. In the French GELA trial and the GOELAMS trial, this incidence was 14% in the HCT arms and ranged from 1 to 7% in the conventional chemotherapy arms [61,63]. A prospective, multicenter trial by the Italian GITMO group represents the only randomized trial that incorporated RTX in the front-line HCT setting [64]. Newly diagnosed FL patients with high-risk disease received R-CHOP induction therapy followed by either RTX maintenance or intensified chemotherapy with RTX during mobilization and after autoHCT. The 4-year EFS was significantly higher in the HCT arm (61% vs. 28%, $p < 0.001$), with no difference in OS. Molecular remission was significantly higher in the HCT arms (80% vs. 44%, $p < 0.001$) and was the strongest independent predictor of outcome. Patients who relapsed in the R-CHOP arm were crossed over to autoHCT, which resulted in a 3-year EFS of 68% in those patients. Thus, based on the above results, there is no role for autoHCT as consolidation of FL patients in first remission.

Autologous HCT for follicular lymphoma – relapsed disease

For patients with relapsed disease, autoHCT has consistently been shown to improve DFS, with one prospective study showing improved OS. Both prospective and retrospective studies reported

5-year PFS ranging from 40 to 50% and one study showed a 10-year freedom from progression of 48% [61–71]. Optimal patients for autoHCT are those who are not heavily pretreated (i.e., fewer than three prior regimens), patients with chemosensitive disease, and patients who have a lower risk Follicular Lymphoma International Prognostic Index (FLIPI) score at the time of autoHCT (Figure 57.3).

The largest retrospective series came from the EBMT and reported the outcomes of 693 FL patients who underwent autoHCT [69]. The 10-year PFS and OS were 31 and 52%, respectively, with an NRM of 9%. The relapse incidence was 54%, with relapse occurring at a median of 1.5 years (range 1 month–13.5 years) after autoHCT. By multivariate analysis, older age, chemoresistant disease, and use of a TBI-based conditioning regimen correlated with inferior survival. The incidence of a second malignancy was 9% and occurred at a median of 7 years after HCT. Another large retrospective series of 241 FL patents who underwent autoHCT reported a 10-year OS and PFS of 75 and 49%, respectively [70]. The relapse incidence was 47%, with a median time to relapse of 20 months (range 2–128 months). Five patients developed a therapy-related malignancy. There has been only one randomized study, known as the CUP (chemotherapy versus unpurged versus purged arm), that prospectively addressed the role of autoHCT versus standard therapy in relapsed FL patients [67]. A total of 140 FL patients with chemosensitive disease after salvage chemotherapy were randomized to receive further conventional therapy versus autoHCT with a purged graft-versus-autoHCT with an unpurged graft. It should be noted that this trial was conducted in the pre-RTX era. The 4-year OS was 46% for the chemotherapy arm, 71% for the unpurged arm and 77% for the purged HCT arm, with a similar advantage seen for the HCT groups with regards to PFS. The impact of ex vivo purging could not be assessed owing to the small sample size in both HCT arms. Unfortunately, this trial closed prematurely owing to poor accrual. There was one large retrospective analysis in the RTX era that included FL patients who received an autoHCT. The GELA/GOELAMS groups evaluated the role of autoHCT versus conventional salvage in 175 FL patients at first relapse who received conventional chemotherapy only or autoHCT [71]. Forty patients (25%) underwent autoHCT. Nearly half of the patients had prior RTX exposure. With a median follow-up of 31 months, the 3-year OS was significantly higher in patients who proceeded to HCT than in patients who did not undergo HCT (92% vs. 63%, $p = 0.0003$). Prior RTX exposure did not affect outcome. It should be noted that the favorable impact of HCT may have been affected by selection bias as only patients responding to salvage therapy proceeded to HCT.

Based on the current literature, the best candidates for autoHCT are relapsed FL patients who are chemosensitive, had fewer than three prior regimens, and who are less than 70 years old. However, for patients with limited stage at relapse, involved field radiotherapy and/or conventional treatment should be considered.

Allogeneic HCT for follicular lymphoma

AlloHCT is the only known curative therapy for patients with FL. FL patients who underwent myeloablative alloHCT demonstrated lower relapse rates than autoHCT recipients [72,73]. However, the high NRM related to ablative regimens was prohibitive and offset the benefit of a lower relapse risk. Two large registry studies by the CIBMTR and the EBMT compared the outcomes of relapsed FL patients who underwent either autoHCT or myeloablative alloHCT [24,72]. In both studies, the relapse risk was significantly lower in the alloHCT group than in the autoHCT patients, but this did not translate into improved OS in the alloHCT patients owing to the higher NRM. The OS for both the autologous and allogeneic groups ranged from 50 to 62% in both studies. Three single-institution retrospective analyses with myeloablative regimens have reported durable remissions in FL patients, with 5-year EFS ranging from 45 to 75% and with outcomes consistently dependent on chemosensitivity at the time of alloHCT [74–76].

Reduced-intensity allogeneic HCT

RIC has been increasingly offered to FL patients and the results have shown durable remissions and less NRM compared with myeloablative regimens. The use of RIC regimens has broadened patient eligibility and usually includes patients older than 70 years of age, patients who had failed a prior autoHCT, and patients with comorbid conditions who otherwise would not be eligible to receive an ablative regimen.

Table 57.3 provides outcomes in four selected prospective trials of FL patients undergoing RIC alloHCT. All trials included patients who had failed a prior autoHCT and utilized a fludarabine-based preparative regimen [77–80]. With a median follow-up ranging from 2 to 9 years, the DFS/EFS ranged from 57 to 85% and the OS ranged from 54 to 88%. Chemosensitivity at the time of HCT was a consistent predictor of outcome. The trial by the M.D. Anderson Cancer Center group had the longest follow-up of 107 months and incorporated the FCR (fludarabine, cyclophosphamide, RTX)

regimen [80]. This regimen included high doses of RTX in which three or the four planned doses were given at a dose of 1000mg/m^2. The 11-year EFS and OS were 72 and 78%, respectively, with only three relapses observed. Based on these impressive results, the BMT CTN conducted a phase II multicenter trial using the same FCR regimen in relapsed FL patients with chemosensitive disease and who had either a matched related or matched unrelated donor identified. Accrual completed in late 2012 and results are eagerly awaited.

The EBMT retrospectively analyzed the outcomes of 164 patients who had matched sibling donors with the specific goal of assessing the impact of in vivo T-cell depletion (TCD) [81]. In this report, patients were divided into three groups: patients who received antithymocyte globulin (ATG) ($n = 46$) or alemtuzumab ($n = 42$) as part of the preparative regimen and a third group ($n = 76$) who received neither agent. Although the patients in the TCD group experienced significantly lower incidences of acute and chronic GVHD compared with the non-TCD recipients, no observed difference in NRM was seen between the TCD and non-TCD groups. However, a significantly higher relapse rate was see in the TCD group (28% vs. 14%, $p = 0.05$). Disease status at HCT was the strongest predictor of all outcomes, including PFS, OS, NRM, and relapse. A retrospective report from the CIBMTR of FL patients who underwent alloHCT with either an ablative or an RIC regimen also further established that chemosensitivity rather than the intensity of the conditioning regimen was a stronger determinant of outcome [82].

The CIBMTR and EBMT directly compared the outcomes of FL patients who underwent either myeloablative or a RIC alloHCT in separate registry analyses. In both reports, the RIC recipients were significantly older and a higher proportion had failed a prior autoHCT compared with the ablative recipients. The CIBMTR analyses included only matched related donors and reported no difference in PFS and OS based on intensity of the conditioning regimen [83]. However, the RIC group had a significantly higher risk of progression. The EBMT report was limited to patients with unrelated donor grafts [84]. In contrast to the CIBMTR report, recipients of the RIC regimens had a lower NRM and experienced a significantly improved PFS and OS by multivariate analysis, although relapse was comparable in the two groups. These findings suggested that an unrelated donor graft may confer a more robust GVL effect. In both the CIBMTR and EBMT reports, chemoresistance and a lower performance status adversely affected outcomes.

In summary, both retrospective and prospective trials reveal that chemosensitivity rather than conditioning intensity is the most reliable predictor prior to alloHCT. Therefore, there are few indications for an ablative regimen outside of a clinical trial.

Novel conditioning regimens

For patients with chemorefractory disease, options are more limited. Therefore, novel regimens have been explored to augment cytoreduction while limiting toxicity, most prominently the use of radioimmunotherapy. Radioimmunotherapy has proven efficacy in the treatment of B-cell lymphomas, including in patients who are refractory to RTX and combination chemotherapy [85]. The M.D. Anderson group tested the novel YFC ([^{90}Y]ibritumomab tiuxetan, fludarabine, cyclophosphamide) regimen in 26 patients with advanced FL including 10 who were chemorefractory [80]. With a median follow-up of 33 months, the 3-year PFS for the chemorefractory and chemosensitive patients were 80 and 87%, respectively, with a 1-year TRM of 8%. A German group reported the results of a prospective trial that used an RIC regimen comprised of [^{90}Y]ibritumomab tiuxetan, fludarabine and low-dose TBI in 40 patients with advanced NHL, including 17 with FL [86]. All patients either had refractory disease or had relapsed after prior autoHCT. The 2-year OS and EFS for the FL patients were 67 and 57%, respectively. However, the 2-year NRM was 45% for all patients, with infection being the leading cause of death.

Another strategy for FL patients with advanced disease is tandem autoHCT followed by RIC alloHCT. A Canadian group prospectively enrolled 27 FL patients with chemorefractory and transformed disease [87]. The 3-year PFS and OS were both 96%, with one death attributed to NRM. A retrospective Italian series reported the results for 34 high-risk NHL patients, including 14 with FL who also underwent tandem autoHCT followed by RIC alloHCT [88]. With a median follow-up of 4 years, the 5-year OS and PFS were 77 and 68%, respectively. The 2-year TRM was 6%. These encouraging results suggest that perhaps the intense cytoreduction conferred by the high-dose chemotherapy with autoHCT followed by eradication of minimal residual disease via the GVL effect may overcome chemoresistance. The low TRM is also encouraging.

Maintenance therapy after HCT

Strategies to eradicate minimal residual disease after HCT leading to extension of remission duration are paramount, as relapse remains the primary cause of treatment failure after autoHCT. Rituximab (RTX) represents an ideal agent for this purpose owing to its tolerability and its immune-mediated mechanism of action. The safety and feasibility of maintenance therapy with RTX after autoHCT have been reported in several phase II trials with patients with MCL, FL, and DLBCL [89–91]. In these early trials, the most common adverse effects of maintenance RTX included prolonged neutropenia and prolonged hypogammaglobulinemia. Severe infections were seen in some but not all of the trials, despite the impaired immune reconstitution.

There have been two large multicenter randomized trials that studied the impact of RTX maintenance therapy after autoHCT for patients with DLBCL. The GELA group reported the results for 476 patients with newly diagnosed high-risk DLBCL who were randomized to induction therapy with either ACE [Adriamycin (doxorubicin), cyclophosphamide, etoposide] or ACVBP [Adriamycin (doxorubicin), cyclophosphamide, vindesine, bleomycin, prednisone] [92]. A total of 330 patients proceeded to autoHCT. After HCT, 269 patients underwent a second randomization to maintenance RTX or observation. After a median of 4 years of follow-up from the second randomization, there was no significant difference in the primary end-point of EFS between the RTX arm and the observation arm.

As mentioned earlier, the CORAL study was a large European intergroup trial eligible to DLBCL patients with relapsed or primary refractory disease. After a first randomization that determined the administered salvage regimen prior to autoHCT, a second randomization assigned patients to maintenance RTX or observation after HCT [16]. No differences were observed in EFS, PFS, or OS between the maintenance and observation arms. The 4-year post-HCT EFS was 52% in the maintenance arm versus 53% in the observation group ($p = 0.7$). Adverse events, most of which were infection, were significantly higher in the RTX maintenance arm.

The EBMT conducted the first prospective randomized trial exploring the efficacy of RTX when administered as an in vivo purging agent prior to mobilization of hematopoietic stem cells and as post-HCT maintenance to consolidate remission [93]. A total of 280 patients with chemosensitive relapsed FL were enrolled. In the first randomization that occurred after salvage therapy, patients received RTX weekly with four doses or observation prior to mobilization. After HCT, patients underwent a second randomization to receive RTX every 2 months for 4 infusions or observation. There was no significant difference in PFS between the purging and no purging groups, but maintenance therapy had a significant effect on 10-year PFS (54% vs. 37%, $p = 0.012$) in favor of the maintenance arm. A higher incidence of neutropenia was seen in the RTX maintenance arms.

Hence definitive conclusions cannot be drawn based on the emerging data on RTX maintenance therapy after autoHCT. Immunotherapy options with interleukin-2 (IL-2) and interferon-α as post-HCT maintenance versus observation have also been explored in randomized trials [94,95]. Treatment with IL-2 alone showed no difference in OS or PFS in a randomized Southwest Oncology Group (SWOG) trial, but the combination of IL-2 and interferon-α improved OS in another trial reported from Israel. Lenalidomide, an oral immunomodulator, has potential as a maintenance agent owing to its reported activity as a salvage agent for NHL patients relapsed after autoHCT [96]. Ibrutinib, a selective and covalent inhibitor of Bruton's tyrosine kinase enzyme, has impressive activity against B-cell malignancies and represents another oral agent that may eventually be explored in the maintenance setting [97].

HCT for transformed lymphoma

For patients with FL, the risk of histologic transformation (HT) to a more aggressive histology is estimated to be 20% at 5 years and 30% at 10 years, and is often associated with a poor prognosis. The median survival after transformation has been reported to be 1–2 years, although outcomes are thought to be improving in the RTX era [98,99]. There is no standard treatment for HT patients and the choice of treatment depends on therapies previously delivered. Most patients are treated with an RTX plus an anthracycline-containing regimen as front-line therapy. Retrospective data suggest that survival after HT is significantly longer in patients who received RTX than in transformed patients who did not receive RTX [98].

High-dose chemotherapy with autoHCT has resulted in prolonged PFS in patients with HT, although most of the studies were in the pre-RTX era and all were retrospective. The 5-year PFS ranged from 25 to 47% with OS ranging from 37 to 58% in these series [100–103]. The only prospective series came from Norway, where 47 patients with HT underwent salvage chemotherapy with responding patients proceeding to autoHCT [104]. For the 30 patients (63%) who proceeded to autoHCT, the 5-year PFS and OS were 32 and 47%, respectively, with a median OS of 47 months. For the 17 patients who did not proceed to HCT, the median OS was only 10 months. Inferior survival outcomes were seen in patients who had received two or more courses of chemotherapy prior to HCT compared with patients who had received only one prior regimen. The first report describing the impact of RTX in the setting of autoHCT for transformed patients came from the University of Rochester, in which 18 patients received RTX-containing therapy before or after HT and then proceeded to autoHCT [105]. The 2-year PFS and OS were 59 and 82%, respectively. For the six patients who did not receive RTX pre-transformation, a significantly better 2-year PFS was seen post-HCT compared with the 12 patients who were not exposed to RTX before transformation. This observation is similar to the results seen in the CORAL study, where PFS after autoHCT was inferior in patients exposed to RTX prior to relapse of DLBCL [15]. The Canadian Blood and Marrow Transplant Group published the largest study to date, in which the outcomes of transformed FL patients were compared after alloHCT ($n = 22$), autoHCT ($n = 97$), or conventional chemotherapy with RTX ($n = 53$) [106]. Over 95% of the alloHCT patients received a myeloablative regimen. The outcomes were similar among all three groups, with the 5-year PFS for the alloHCT, autoHCT, and conventional chemotherapy groups being 46, 55, and 40%, respectively, and the corresponding 5-year OS were 46, 65, and 61%. AlloHCT was an independent prognostic factor for improved PFS but the higher TRM offset any OS benefit. The 5-year TRM for the alloHCT group was 23% versus 5% for the autoHCT group. Based on the above results, patients with transformed lymphoma may modestly benefit from autoHCT as it appears to improve OS compared with conventional chemotherapy with RTX. Hence patients with a good performance status and chemosensitive disease should be offered autoHCT early in their course.

There have been only a few retrospective series describing the outcomes of transformed patients after alloHCT and the results overall are only fair at best. The largest series comprised 40 patients with relapsed composite and transformed lymphoma patients (n = 25 transformed) who underwent myeloablative alloHCT [107]. The 5-year EFS and OS were 23%. The 3-year TRM was 36%, with a 5 year relapse incidence of 42%. In another retrospective study, 16 patients with transformed disease underwent RIC alloHCT with disappointing results. The 3-year PFS and OS were 18 and 21%, respectively, with an NRM of 42% [108]. Tandem autoHCT followed by RIC alloHCT has also been studied in 10 patients with transformed disease. The 4-year PFS and OS were both an encouraging 70% [109]. Based on these limited results and poor outcomes, alloHCT should not be routinely offered to transformed patients except with within the context of a clinical trial.

Burkitt lymphoma

Burkitt lymphoma (BL) is a highly aggressive but curable mature B-cell NHL that accounts for less than 5% of all NHLs in adults. The median age at diagnosis is 45 years and patients often present with bulky extranodal disease, CNS involvement, and a rapidly progressive clinical course. BL cells display a high proliferation index with a Ki-67 proliferation index of nearly 100%. The hallmark of BL is the overexpression of MYC due to a balanced translocation between the MYC/8q24 locus and an immunoglobulin gene, most commonly IgH t(8;14)(q24;q32) [110]. Front-line therapy of BL is comprised of brief-duration, high-intensity chemotherapy that includes RTX and yields CR rates close to 100%, with cure rates approaching 65–70% [111,112]. AutoHCT has not improved outcome compared with front-line therapy.

There have been few reports and no randomized studies evaluating the role of autoHCT in patients with BL. With the exception of a recent CIBMTR analysis [113], none of the reports published to date included patients who had previously received RTX, which limits the applicability of such results. The feasibility of autoHCT as front-line therapy for BL has been established, but none of the reports have demonstrated superior outcomes compared with the current results seen with modern front-line chemoimmunotherapy alone. The largest and most recent retrospective series came from the CIBMTR, which reported the results for 113 BL patients who underwent autoHCT in various states of remission [113]. Only 5% of the 113 BL patients had received RTX prior to HCT. The 5-year OS was 83% for patients in CR1, 53% for patients in subsequent CR, and 22% for patients not in CR. Relapse or progression was the primary cause of death for all groups, with a significantly higher relapse incidence at 5 years in the CR1 versus non-CR1 group (61% vs. 18%, respectively, $p < .0001$). This retrospective analysis included the period from 1985 to 2007, in which only 19% of patients underwent HCT after 2001. Hence the use of autoHCT has significantly declined over time. The EBMT conducted a retrospective analysis of 117 adult BL patients who received autoHCT in which 70 patients (60%) were in CR1 [114]. The 3-year OS and PFS were 72 and 73%, respectively. For patients in chemosensitive relapse, the 3-year OS was 34%. Disease bulk was predictive of outcome, as patients with bulky disease had inferior outcomes. However, none of the patients in the EBMT study had received RTX. These results indicated that autoHCT in CR1 yielded comparable survivals before the use of modern brief, high-intensity regimens that incorporated RTX. Hence autoHCT in CR1 does not offer an additional advantage over current dose-intensive regimens.

Results for BL patients with alloHCT are not noticeably superior to autoHCT outcomes, although in most series the alloHCT recipients had either more advanced disease or chemoresistant disease or were more heavily pretreated compared with autoHCT patients. The above-mentioned CIBMTR analyses included 128 BL patients who underwent alloHCT [113]. The 5-year OS for patients in CR1, subsequent CR, and not in CR were 53, 28, and 12%, respectively. As observed with the autoHCT recipients in this CIBMTR report, progression/relapse was significantly lower in the remission patients than the non-remission patients, 27% versus 51%, respectively. Hence the alloHCT cohort was not directly comparable to the autoHCT group. The EBMT analyzed outcomes of 1185 NHL patients after alloHCT, including 71 patients (6%) who had BL [24]. The 4-year OS and PFS were 37 and 35%, respectively, with a TRM of 31% for the BL patients. Disease status at transplant was the most significant prognostic factor by multivariate analysis.

In summary, based on current results, there is no role for autoHCT or alloHCT as consolidative therapy for the treatment of BL. For patients with relapsed disease, achieving a subsequent CR prior to HCT is the most important determinant of outcome prior to either autoHCT or alloHCT. As mentioned above, the results obtained from retrospective analyses cannot accurately gauge whether autoHCT or alloHCT is more suitable, since the alloHCT patients had more high-risk features. Patients who relapse after modern intensive RTX-containing regimens are a subset of patients with particularly aggressive disease and should be offered alloHCT if a suitable donor is available. For patients with a matched sibling or matched unrelated donor, alloHCT with myeloablative conditioning is preferred. However, autoHCT is a suitable option if an appropriate donor is not available and a second CR can be achieved prior to autoHCT.

Lymphoblastic lymphoma

Lymphoblastic lymphoma (LBL) is a rare, aggressive form of NHL that is morphologically indistinct from acute lymphoblastic leukemia (ALL), as both entities express lineage-specific markers and terminal deoxynucleotidyl transferase (TdT) [3]. The clinical features used to distinguish LBL from ALL include <25% marrow involvement, predominantly nodal disease involvement, and a large mediastinal mass. LBL is treated very similarly to ALL with chemotherapy phases consisting of induction, intensification, consolidation, CNS prophylaxis, and maintenance therapy [115]. These multidrug regimens yield CR rates >90% and OS of 60–70% at 3 years [116,117]. There is no definitive evidence that autoHCT or alloHCT improves survival if offered in CR1. The Vancouver group conducted a retrospective analysis of 34 newly diagnosed LBL patients who proceeded to autoHCT or alloHCT soon after induction therapy [118]. For the 29 patients who actually proceeded to HCT (25 autologous recipients, four allogeneic recipients), the 4-year OS and EFS were 79 and 73%, respectively, with a median follow-up of 51 months. All four alloHCT patients were alive and disease free whereas the autoHCT group had a 4-year EFS of 69%. The GOELAMS group identified high-risk patients who underwent autoHCT in first remission and compared their outcomes with those of standard risk patients randomized to either conventional chemotherapy or autoHCT. There were no differences in outcomes among all three groups, although the definitions of risk factors among the groups were not consistent.

The CIBMTR published results for one of the largest retrospective series of LBL patients in various states of remission or relapse, which included 128 autoHCT patients and 76 patients who received alloHCT with a matched sibling donor [119]. The 5-year relapse incidence was significantly lower in the alloHCT than the autoHCT group (34% vs. 56%, $p = 0.004$), but the OS was comparable (39% vs. 44%, $p = 0.47$) due to the significantly higher TRM in the alloHCT recipients (25% vs. 5%, $p = 0.0003$). No prospective trial with alloHCT has been reported to date. Therefore, for LBL patients, HCT should be reserved for patients who are induction failures or beyond CR1. For young patients with a suitable donor, alloHCT would generally be recommended to take advantage of the GVL effect. However, if a donor is not available or if a patient is unable to proceed to alloHCT, autoHCT is also acceptable.

Involved field radiotherapy after HCT

Retrospective analyses show that ~50–75% of failures after autoHCT occur at prior sites of disease. Thus, involved field radiation therapy (IFRT) is a logical strategy to improve local control after autoHCT. No studies have prospectively evaluated the impact of IFRT in NHL patients after HCT, but several retrospective series have yielded mixed results. Some series have unequivocally demonstrated improved local control and PFS with the use of IFRT but without definitive impact on OS, while other studies have shown a positive impact on OS [120–123].

A recent study of a large, retrospective series of 164 patients examined the effect of IFRT in DLBCL patients after autoHCT and showed a significantly improved survival outcome. A total of 79 patients (48%) underwent IFRT after autoHCT. IFRT reduced local failure by only 10% ($p = 0.17$), but on multivariate analysis IFRT was associated with a significantly improved OS and disease-specific survival [120]. Additionally, a CIBMTR report on 184 patients with primary refractory diffuse aggressive NHL who received IFRT after autoHCT showed that the omission of IFRT before or after HCT was an adverse prognostic factor [123]. The timing of IFRT in the HCT setting is also a matter of debate, as pre-transplant IFRT reduces disease volume prior to HCT but the incidence of pneumonitis and venocclusive disease may be increased. Post-transplant IFRT will have less impact on the timing of HCT and allows for refinement of radiation dose and field according to response after HCT. Despite the lack of randomized trials, IFRT is routinely recommended owing to its benefit in achieving local control and its ability to convert patients with persistent disease to CR after HCT. It is often administered 1–3 months post-HCT when blood counts have fully recovered.

Conclusion

NHL patients are a heterogeneous group, hence the recommendation of autoHCT or alloHCT in NHL patients must be tailored to the specific histology, disease status, age, and performance status of the patient. The addition of RTX to front-line therapy in patients with B-cell NHL has improved response rates and survival outcomes. However, an increasing amount of data has shown that prior RTX exposure is an adverse risk factor for relapsed DLBCL patients and for transformed NHL patients who subsequently proceed to autoHCT. It is still a matter of debate as to the optimal therapy for this specific patient group and investigation therapies should also be considered in this population. However, autoHCT remains the standard of care for relapsed DLBCL patients and confers long-term DFS in a significant number of patients with chemosensitive disease. AutoHCT also can extend DFS and OS in MCL patients when offered as consolidation therapy during CR1 and should be considered for all patients <65 years old and without significant comorbidities.

AlloHCT is not commonly offered as front-line therapy for B-cell NHL patients owing to the high NRM compared with autoHCT. RIC alloHCT can salvage a subset of patients who relapse after autoHCT, provided that chemosensitive disease can be demonstrated prior to alloHCT. The most challenging subtype are the "double hit" aggressive lymphomas. Unfortunately, it is not clear that autoHCT or alloHCT can alter the poor prognosis associated with this group of patients. In summary, the outcomes of B-cell NHL patients continue to improve and the number of eligible patients for HCT continues to grow owing to improved supportive care, more precise donor matching, and an increasing availability of donors.

CHAPTER 58

Hematopoietic Cell Transplantation for Non-Hodgkin Lymphoma (T Cell)

Jasmine Zain and Sandra H. Thomas
City of Hope Medical Center, Duarte, CA, USA

Introduction

Mature T-cell and natural killer (NK)-cell non-Hodgkin lymphomas (T-cell NHLs) comprise about 12% of all NHLs and 15–20% of aggressive lymphomas worldwide [1,2]. T-cell NHL exhibits great morphologic diversity and histological variation even within individual disease entities; the current 2008 World Health Organization (WHO) *Classification of Tumours of Haematopoietic and Lymphoid Tissues* recognizes 20 types of mature T- and NK-cell neoplasms and three provisional entities [3]. The systemic disease histologies are often collectively referred to as peripheral T-cell lymphomas (PTCLs) and the most common nodal subtypes typically include peripheral T-cell lymphoma not otherwise specified (PTCL-nos), anaplastic large-cell lymphoma (ALCL), and angioimmunoblastic T-cell lymphoma (AITL); however, there are also geographic pockets of high-prevalence endemic disease, especially for human T-cell lymphotropic virus 1 (HTLV-1)-associated T-cell lymphoma/leukemia, Epstein–Barr virus (EBV)-associated NK/T-cell nasal type, and enteropathy-associated T-cell lymphoma (EATL) [4]. Cutaneous T-cell lymphomas (CTCLs) represent a clinically distinct subgroup of T-cell NHLs [5], generally having more indolent behavior, with the exception of a few subtypes, including Sézary syndrome and transformed mycosis fungoides.

For aggressive lymphomas, T-cell phenotype tends to confer poorer clinical outcomes than does B-cell phenotype, with the exception of ALCL [6,7]. The most aggressive T-cell NHL histologies include hepatosplenic T-cell lymphoma (HSTCL), γ/δ T-cell malignancies and NK/T-cell lymphomas [8], with long-term survival at 5 years only 10–30% for most histologies [4]. Advanced disease stage, high prognostic index at presentation [9], and inherent chemomoresistance [10] contribute to the unsatisfactory outcomes for this disease group. Recently identified biomarkers with potential diagnostic and prognostic implications for PTCL include cell lineage markers such as γ/δ T-cell receptor (TCR) rearrangement; NK-cell receptors and killer immunoglobulin-like receptors (KIRs); cytotoxic markers such as TIA-1, granzyme and perforin; and follicular helper T-cell markers such as CXCL13 and PD-1 [11]. Table 58.1 provides the frequency distribution and 5-year overall survivals for the major PTCL histologies as determined by the International T-Cell Lymphoma Project [4].

Patients with aggressive CTCL histologies, Sézary syndrome, and advanced mycosis fungoides typically have prolonged disease courses with multiple failed treatment regimens, ultimately resulting in chemoresistance. Table 58.1 also provides frequency distribution and disease-specific survival data for the cutaneous T-cell NHLs as determined by the WHO and European Organization for Research and Treatment of Cancer (EORTC) classification [5].Current therapeutic strategies for T-cell NHL remain poorly defined and tend to be extrapolated from treatment paradigms for B-cell NHL. As a result, relapsed and chemorefractory disease remain significant clinical dilemmas in the care of these patients.

Diagnosis and treatment of T-cell NHL

Current treatment paradigms for T-cell NHL are grossly inadequate, as indicated by the poor overall outcomes (Table 58.1). Despite a lack of randomized prospective trials for these rare diseases, the National Comprehensive Cancer Network (NCCN) has created treatment guidelines using available clinical data and the principles of evidence-based medicine [12]. These guidelines are acceptable as current standard of care and are modified in real time as new data emerges.

As per the NCCN guidelines, most histologic subtypes are treated similarly with the exception of a few clinically distinct subtypes: anaplastic lymphoma kinase (ALK)-positive ALCL, which has excellent prognosis compared with other subtypes; extra nodal NK/T-cell lymphoma nasal type, which is radiosensitive; and adult T-cell leukemia/lymphoma (ATLL), which is considered uniquely both by the NCCN and in this book (Chapter 69). At the time of presentation, patients undergo induction therapy that may be consolidated with high-dose therapy and autologous hematopoietic cell transplantation (autoHCT) if remission is achieved. At the time of relapse, a treatment plan is formulated based on whether or not the patient is a transplant candidate.

Disease characteristics and recommended treatments for the three major treatment groups follow.

PTCL-nos excluding CTCL and NK/T-cell lymphomas

PTCL-nos is a heterogeneous group of diseases that includes both nodal and extranodal presentations. The median age at presentation is less than 35 years for ALK^+ ALCL and over 60 years for most other subtypes, with a slight male predominance. T-cell lymphomas tend to present with a higher International Prognostic Index (IPI) and are more likely to have systemic involvement including bone marrow,

Table 58.1 PTCL and CTCL frequency and survival

PTCL histology[a]	Frequency (%)	5-year OS (%)
Peripheral T-cell lymphoma – nos	25.9	32
Angioimmunoblastic	18.5	32
Extranodal NK/T-cell lymphoma	10.4	32
Nasal type NK/T		42
Extra-nasal type NK/T		9
Adult T-cell leukemia/lymphoma	9.6	14
Anaplastic large cell lymphoma, ALK^+	6.6	70
Anaplastic large cell lymphoma, ALK^-	5.5	49
Enteropathy-type T-cell lymphoma[c]	4.7	20
Primary cutaneous ALCL	1.7	90
Hepatosplenic T-cell lymphoma	1.4	7
Subcutaneous panniculitis-like lymphoma	0.9	64
CTCL histology[b]	**Frequency (%)**	**5-year DSS (%)**
Mycosis fungoides	61.2	88
Lymphomatoid papulosis	16.0	100
Primary cutaneous ALCL	9.9	95
Sézary syndrome	3.5	24
Primary cutaneous PTCL, unspecified	3.2	16
Primary cutaneous CD4^+ small/medium pleomorphic[d]	2.6	75
Subcutaneous panniculitis-like lymphoma	1.2	82
Primary cutaneous aggressive CD8^+ T-cell lymphoma[d]	0.9	18
Primary cutaneous γ/δ T-cell lymphoma[d]	0.9	Not reached
Primary cutaneous NK/T-cell lymphoma, nasal type	0.5	Not reached

OS, overall survival; DSS, disease-specific survival.

[a] All PTCL data are from 1314 patients from 22 worldwide centers on the International Peripheral T-cell and Natural Killer/T-cell Lymphoma Study [94].

[b] All CTCL data are from 1905 patients in the Dutch and Austrian Cutaneous Lymphoma Group Registry (of whom 1476 were T or NK cell) described in the WHO–EORTC classification for cutaneous lymphomas [5].

[c] The classification Enteropathy-type T-cell lymphoma used in this study is not the same as the WHO 2008 enteropathy-associated T-cell lymphoma (EATL), but was a generic category that included most T-cell lymphomas involving the intestines, including EATL and γ/δ T-cell lymphoma.

[d] Provisional classification.

skin, and central nervous system (CNS) compared with B-cell lymphomas. The broad range of disease subtypes and clinical behavior poses a challenge to studying treatment for these diseases [13].

Initial treatment with anthracycline-containing regimens shows favorable outcomes for patients with ALK^+ ALCL, but the data for other histologies are not convincing, and treatment on clinical trial is recommended if available. A retrospective analysis from a large multicenter study demonstrated no difference in outcomes using anthracycline- or non-anthracycline-containing regimens, with 5-year survival for most histologies remaining below 30% [4]. In contrast, a more recent retrospective report of 442 PTCL patients from North America shows that up front anthracycline-containing regimens are associated with an improved PFS (35% vs. 2%) and OS (60% vs. 2%), even in high risk patients [14]. A German retrospective analysis s did show an event-free survival (EFS) benefit for patients younger than 60 years of age who received etoposide-containing regimens for patients with ALCL [15]. Presently, CHOP [cyclophosphamide, hydroxydaunomycin (doxorubicin), vincristine (Oncovin), prednisone] or CHOP-like regimens remain the backbone of upfront therapy. Attempts to improve outcomes include the use of targeted agents in addition to CHOP-like regimens, such as denileukin diftitox, pralatrexate, alemtuzumab, and brentuximab vedotin. While some trials are ongoing, the findings so far have not been convincing enough to change treatment paradigms. Attempts to use non-CHOP-based regimens in the upfront setting have not been successful; for example, the PEGS (platinum, etoposide, gemcitabine, methylprednisolone) induction regimen results in a 2-year progression-free survival (PFS) of 12% and an overall survival (OS) of 30% [16]. It is possible that as new targeted agents are developed for T-cell lymphomas, novel combinations of these agents with or without cytotoxic chemotherapy will prove to be more effective than chemotherapy alone.

The NCCN guidelines recommend consideration of high-dose therapy and autoHCT as consolidation of first remission for eligible patients with most histologies of PTCL. The only exceptions are ALK^+ ALCL where upfront CHOP-like therapy results in a 5-year OS of over 80%.

NK/T-cell lymphoma nasal and extranasal type

NK/T-cell lymphomas are rare tumors primarily seen in Asia and South and Central America. They are categorized as extranodal NK/T-cell nasal type leukemia (ENKL) and aggressive NK-cell leukemia (ANKL). The median age at presentation is 43 years with a male predominance. These tumors exhibit angiodestructive behaviors, with a predilection for the nasal cavity and paranasal sinuses, but can present at other sites, including skin, gastrointestinal tract, testis, kidney, and upper respiratory tract. NK/T-cell lymphomas are associated with EBV, express P-glycoprotein and have an aggressive clinical course [17].

NK/T-cell tumors are extremely radiosensitive and where possible radiation should be part of the managment plan. For localized disease of the nasal type without any local tumor invasion or nodal involvement, radiation therapy given at doses of >50Gy provides improvement in survival [18]. Similarly, there is an improvement in EFS and OS when radiation therapy is given early or in the upfront setting, either concurrently or sequentially, with combination chemotherapy. For advanced-stage disease or extranasal variants, it is difficult to deliver localized radiation therapy, hence treatment relies primarily on chemotherapy; Recommended regimens incorporate agents like asparaginase, methotrexate, etoposide and ifosphamide [19]. Except for stage I disease, it is recommended that once a patient reaches a state of remission, HCT should be considered [17].

CTCL and Sézary syndrome

Cutaneous T-cell lymphomas have a more indolent clinical course characterized by multiple relapses and occasional spontaneous remissions, with the exception of primary cutaneous γ/δ T-cell lymphoma. The unique biologic features of this group of diseases include primarily skin manifestations, waxing and waning of lesions, relative chemoresistance of tumors, and an immunosuppressive disease state. The combined immunosuppression and breach of the skin barrier are associated with high infection rates, particularly with staphylococcal and streptococcal species, and successful treatment of these infections results in improvement of disease flares. The clinical course varies widely, but only 5–10% of patients develop more advanced aggressive diseases, such as transformed mycosis fungoides and Sézary syndrome.

Most patients experience prolonged survival with the use of only skin-directed therapies and may not require any systemic therapy for extended periods. Treatments can be combined to optimize therapeutic effects and minimize side effects and can be reinitiated at a later time if the disease progresses after an initial response. Supportive treatments play an important role in the overall management and include the use of emollients and ointments, antipruritic agents, and infection control/prevention. Owing to the indolent nature of the disease, maintenance treatment or tapering of the regimen plays an important role and should be considered in patients achieving remission. For most modalities, efficacy data are derived from small studies with a heterogeneous population of patients and an evolving staging system. Despite this, treatment recommendations have been developed by the NCCN [12], the United States Cutaneous Lymphoma Consortium [20], and the EORTC [21].

Skin-directed therapies alone are recommended for stages IA, IB, and IIA, but may also be used in addition to systemic therapies for relapsed or advanced disease. Topical therapies include steroids, nitrogen mustard (mechlorethamine), carmustine, imiquimod, and bexarotene. Light and radiation therapies include phototherapy [UVB, narrow-band UVB, PUVA (psoralen UVA irradiation)] and total skin electron beam therapy (TSEB) for generalized skin involvement. Local radiation can be used to treat ulcers, tumors, or transformed disease.

Systemic therapies are indicated for stages IIB and higher, folliculotropic subtype or transformed disease, as well as after failure of skin-directed therapies in earlier stage disease. These include the US Food and Drug Administration (FDA)-approved treatments bexarotene, denileukin diftitox, vorinostat, romidepsin, and extracorporeal photopheresis (ECP). Other therapies include interferon, bortezomib, alemtuzumab and single-agent chemotherapies including pralatrexate, methotrexate, liposomal doxorubicin and gemcitabine. Sézary Syndrome patients respond to ECP either alone or in combination, alemtuzumab, and romidepsin. Combination chemotherapies used for the treatment of aggressive lymphomas can be applied in advanced-stage CTCL or transformed disease. Brentuximab vedotin has shown promising activity in CD30$^+$ cutaneous lymphoproliferative disorders such as mycosis fungoides [22]. Allogeneic transplant is reserved for more advanced disease and is discussed below.

HCT for systemic or peripheral NK/T-cell lymphoma (PTCL)

Autologous HCT

High-dose therapy and autoHCT are used extensively to treat patients with PTCL, both in the relapsed setting and as first-line consolidation. AutoHCT in first remission was first explored due to low response rates to primary therapy and frequent early relapses. The data to support this is presented below.

Two randomized trials by the French Groupe d'Etude des Lymphomes de l'Adulte (GELA) in the late 1990s examined the role of autoHCT for aggressive NHLs including T-cell lymphomas. LNH-87-02 included 452 patients with high-risk lymphoma, 17% with T-cell phenotype, who achieved CR and were randomized to either a combination chemotherapy consolidation regimen or high-dose chemotherapy followed by autoHCT [23]. The autoHCT arm was shown to have a better outcome than the chemotherapy arm with an 8-year OS of 64% versus 49%. In LNH-93, 370 patients were enrolled and 23% had T-cell phenotype [24]. The authors compared standard induction consolidation at that time with a shortened induction and autoHCT consolidation. In this approach, the transplant arm yielded an inferior 5-year OS of 60% versus 46%. Notably, the T-cell phenotype was clearly associated with poor prognosis in this trial ($p = 0.009$). In 2004, the data from both GELA trials was pooled for all subtypes of NHL to determine whether there was a benefit to autoHCT in CR1 [25]. There were 51 (16%) patients with T-cell lymphomas including precursor T-cell lymphomas and ALK$^+$ ALCL, but no benefit was evident for autoHCT. It is difficult to apply these data to current practice, as these trials were not designed to look specifically at PTCL and included aggressive histologies such as lymphoblastic lymphoma. Also, the LNH-87 and LNH-93 trials used regimens no longer in standard practice, which may compromise their applicability to modern regimens.

Retrospective studies

Over the past 20 years, there have been over 24 retrospective studies with more than 1400 PTCL patients, assessing the role of autoHCT for the treatment of PTCL at various disease stages. These studies have an inherent selection bias in terms of favoring younger, healthier patients who are able to undergo transplant. In addition, most studies are heterogeneous in terms of patient populations, upfront treatment regimens, and conditioning regimens. Almost all studies exclude patients with leukemic variants of PTCL and are limited to otherwise healthy patients with median ages under 60 years. There are several excellent reviews that describe these studies in detail [26,27]. Data from the larger studies in recent years are summarized in Table 58.2.

Table 58.2 Recent retrospective PTCL trials for autoHCT

Ref.	*n*	Histologies	Disease status at transplant	OS	PFS
Beitinjaneh 2011 [32]	126	42 PTCL-nos, 47 ALCL, 7 ALK$^+$, 15 AITL, 6 NK/T, 6 HSTCL	CR/PR 84% 33% 1st line	39%(4 yr) For CR1 87% (4 yr)	30% (4 yr) For CR1 67% (4 yr)

n, Number of patients; PTCL-nos, peripheral T-cell lymphoma not otherwise specified; ALCL, anaplastic large-cell lymphoma; ALK, anaplastic lymphoma kinase; AITL, angioimmunoblastic T-cell lymphoma; NK/T, NK/T-cell lymphoma; HSTCL, hepatosplenic T-cell lymphoma; CR, complete response; PR, partial response; OS, overall survival; PFS, progression-free survival; yr, year(s).

The advent of the Revised European–American Lymphoma (REAL) and later the WHO classifications provided the impetus to look at the autoHCT experience in NHLs and tease out distinguishing characteristics for the T-cell immunophenotype. Vose et al. [28] first described outcomes for autoHCT performed in the relapsed setting for T-cell phenotype and compared them with aggressive B-cell lymphoma outcomes. In this study, there were 17 T-cell and 24 B-cell patients based on immunophenotype, and the authors found no difference in outcomes in terms of OS and EFS; the 2-year OS was 30–35% for both groups, thus establishing autoHCT as an acceptable treatment option for T-cell NHL. Fanin et al. [29] examined outcomes in 64 patients with CD30$^+$ T- and null-cell ALCL based on the REAL classification, and concluded that the 15 patients transplanted in CR1 had >90% long-term survival. This was the first suggestion that autoHCT might provide cure if performed in CR1 for certain PTCL histologies. In both studies, patients were young, with median ages of 25 and 33 years, in keeping with the practice patterns of that time.

In 2003, Rodriguez et al. [30] analyzed data from 115 PTCL patients (by REAL classification) in the GEL/TAMO (Grupo Español de Linfomas/Trasplante Autólogo de Médula Ósea) database who underwent autoHCT. At 5 years, the median OS was 56% and time-to-treatment failure was 51%. However, the 5-year OS was 80% for those transplanted in CR1 versus 50% for non-CR1, and 0% for patients with refractory disease. Longer survival was associated with age <41 years, transplantation in CR, or chemosensitive disease. Within the same group, Rodriguez et al. [31] reported separately on a cohort of 35 patients who did not achieve remission after anthracycline-based induction therapy. Thirty-one of these patients underwent transplantation and 23 (66%) achieved CR. The 5-year OS was 37% and disease-free survival (DFS) was 55%, indicating that one-third of patients with PTCL who failed to respond to initial chemotherapy could be salvaged with autoHCT. This study also emphasized the superior outcomes obtained from consolidation in first remission.

The largest single-center study of 126 PTCL autoHCT patients was reported by the M.D. Anderson Research Center [32] at the 2011 meeting of the American Society of Clinical Oncology. At the time of transplant, 33% of patients were in CR1, 51% had chemosensitive relapse, and 16% were refractory to therapy. The median follow-up was 39 months, with 4-year OS of 39% and PFS of 30%. The best outcomes were seen in patients transplanted in CR1, with a 4-year OS of 87% and a PFS of 67%. In comparison, the 4-year OS and PFS for patients with chemosensitive relapse was 39 and 36% and for refractory disease 24 and 15%, respectively. This study indicates that although it is possible to achieve long-term remission for chemosensitive relapsed disease with autoHCT in PTCL, the best outcomes are seen for consolidation of first state of remission. The largest registry study to date from the European Group for Blood and Marrow Transplantation (EBMT) was presented as an abstract at the American Society of Hematology meeting in 2008. Nickelsen et al. [33] reported on 424 patients undergoing autoHCT for PTCL with an OS of 62% and a DFS of 50% at a median of 3 years. This study also supported the assertion that the best outcomes following autoHCT are in CR1.

The most common conditioning regimens used for autoHCT in PTCL patients are: BEAM (BCNU, etoposide, Ara-C, melphalan), BEAC (BCNU, etoposide, Ara-C, cyclophosphamide), CBV (cyclophosphamide, BCNU, etoposide), and busulfan (BU)/cyclophosphamide (CY). A fair number of patients have also received total body irradiation (TBI)-based regimens, usually in combination with cyclophosphamide or etoposide or both. The City of Hope group compared the outcomes of 41 patients treated with TBI-based regimens with those of 26 patients with non-radiation-based regimens and reported no differences [34]. The Stanford group questioned the effect of T-cell depletion in a cohort of 53 patients, of whom 86% received a T-cell-depleted graft, but found no differences in outcome [35]. Currently there are no specific recommendations for the choice of a conditioning regimen for this group of patients. The highest transplant-related mortality (TRM) at 11% was reported by Jantunen et al. in a small study of 37 patients [36] that included the uncommon and aggressive EATL. In other sudies, TRM rates range from 3.7% [32] to 7.5% [37]. No information is available on long-term complications as the maximum follow-up is 5 years.

Multiple studies have focused on specific histologies of T-cell NHL. ALCL has been reported by several groups to have superior outcomes compared with non-ALCL histologies [29,33,36–38]. An EBMT Registry study [39] focused on the outcomes of patients with AITL, another common nodal PTCL. In this cohort of 146 patients, about 70% were transplanted in CR1. The 2-year OS and PFS were 67 and 53%, respectively. Patients who were transplanted in CR1 demonstrated a 4-year PFS of 56%, versus 30% for non-CR1 and 23% for relapsed disease. Hence this study supports the use of autoHCT for patients with AITL in CR1. NK/T-cell lymphoma is more common in Asia, and Hwang et al. reported on the use of autoHCT in 10 patients with NK/ T-cell lymphoma [40]. For patients undergoing stem-cell transplant in CR/PR (partial remission), the 5-year OS was 53% compared with only 20% for those not in CR/PR.

Other than transplantation in CR1, there is no real consensus on prognostic factors that affect outcomes after autoHCT in PTCL. Retrospective studies suggest that autoHCT is feasible in patients with PTCL and the 5-year median OS varies from 34 to 70% and EFS from 30 to 61%. However, if transplants are performed in first remission reports show up to 80% 5-year OS and 67% EFS. In most studies, the outcome for refractory or chemoresistant disease remains dismal, with fewer than 15% long-term survivors. The use of autoHCT can salvage about one-third of patients with relapsed chemosensitive disease, again with best outcomes for ALCL, particularly ALK$^+$.

Prospective trials

There is now a substantial body of literature supporting autoHCT in CR1 for PTCL, albeit lacking confirmation by randomized trials. The NCCN guidelines for NHL recommend consideration of autoHCT for patients with PTCL who achieve a CR or PR after primary therapy and are eligible based on age and comorbidity [12]. Exceptions to this approach include ALK$^+$ ALCL, CTCL, and very aggressive T-cell lymphomas (leukemic presentation). The overall prognosis of the ALK$^+$ ALCL subtype is substantially better than those of other T-cell lymphomas, with overall response rates to CHOP-based induction therapy of >90% and a 5-year OS of 70% [41]. AutoHCT in first CR has shown excellent results in ALK$^+$ ALCL patients, but superiority to standard chemotherapy is unproven. Additionally, newer agents targeting CD30 and ALK can provide excellent responses in the relapsed setting [42], thus eliminating the need for aggressive approaches in first CR. Very aggressive and leukemic variants of PTCL, including HSTCL,

Table 58.3 Prospective PTCL trials for autoHCT

Ref.	*n*	Histologies	Induction therapy	Conditioning regimen	Patients transplanted (%)	OS	PFS
d'Amore 2012 [45]	160	Includes ALK$^+$ ALCL, 1° leukemic	Age ≤60 CHOEP 14; age >60 CHOP 14	BEAM/BEAC	72	51% (5 yr)-	44% (5 yr)
Reimer 2009 [46]	83	No ALK$^+$ ALCL	CHOP × 4–6 cycles	TBI/CY	66	48% (3 yr)	36% (3 yr)
Corradini 2006 [47]	62	Includes ALK$^+$ ALCL (30%)	APO alternating with DHAP, or MACOP-B followed by mitoxantrone/Ara-C	BEAM	71	34% (12 yr)	30% (12 yr)
Ahn 2011 [49]	46	25% had NK/T No ALK$^+$ ALCL	CHOP, CHOP-like or non-anthracycline	BU/CY/VP-16	66	57% (5 yr)	55% (5 yr)
Mercadal 2008 [48]	41	No ALK$^+$ ALCL	High-dose CHOP alternating with ESHAP	BEAM/BEAC	41	39% (4 yr)	30% (4 yr)
Rodriguez 2007 [50]	26	No ALK$^+$ ALCL	Mega-CHOP, if PR or SD after 3 cycles, got IFE	BEAM	73	73% (3 yr)	53% (3 yr)

n, Number of patients; ALK, anaplastic lymphoma kinase; ALCL, anaplastic large-cell lymphoma; NK/T, NK/T-cell lymphoma; CHOEP, cyclophosphamide, doxorubicin, vincristine, etoposide, prednisone; CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone; APO, doxorubicin, vincristine, prednisone, DHAP, cisplatin, Ara-C, prednisone; MACOP-B, methotrexate with leucovorin rescue, doxorubicin, cyclophosphamide, vincristine, prednisone, bleomycin; BEAM, BCNU, etoposide, Ara-C, melphalan; BEAC, BCNU, etoposide, Ara--, cyclophosphamide; TBI, total body irradiation; BU, busulfan, CY, cyclophosphamide; VP-16, etoposide; CR, complete response; PR, partial response; SD, stable disease; OS, overall survival; PFS, progression-free survival; yr, year(s).

HTLV-1-associated ATLL, T-cell prolymphocytic leukemia (T-PLL), and primary cutaneous γ/δ T-cell lymphoma, may not benefit from upfront autoHCT. These diseases have a very aggressive clinical course due to inherent chemoresistance and patients tend to experience multiple failures of primary therapy; hence autoHCT approaches have generally not produced long-term remissions in these patients [43,44]. Long-term remissions and improved survival have been seen in patients with these highly aggressive variants following allogeneic transplantation in first remission.

To date, six prospective trials have reported on the use of autoHCT performed in first CR, primarily for nodal PTCL. In all trials described in Table 58.3, patients were induced with chemotherapy, and those who achieved a CR or PR and maintained transplant eligibility received high-dose therapy and autoHCT.

The largest study in this category is a prospective multicenter trial by the Nordic Lymphoma group that took a dose-dense approach to the treatment of PTCL followed by autoHCT [45]. This study of 160 patients has a long median follow up of 5 years. The histological subtypes were distributed as follows: PTCL-nos ($n=62$), ALK$^-$ ALCL ($n=31$), AITL ($n=30$), EATL ($n=21$), panniculitis-like T-cell lymphoma ($n=6$) T/NK nasal-type ($n=5$), and HSTCL ($n=5$). Patients aged 60 years or younger received primary induction therapy with CHOEP-14 (doxorubicin, vincristine, etoposide, prednisone), and those over age 60 years received CHOP-14 (no etoposide). Of the 131 responders to initial therapy, 114 underwent BEAM/BEAC conditioning and autoHCT, after which 90 patients were in CR and nine in PR, at 3 months post-transplant. In the post-transplant setting there were 39 relapses, with 28 in the first 2 years and the remainder as late as 71 months post-transplant. In an analysis of the entire cohort, with a median follow-up of 60 months, the TRM was 4%, OS 51% and DFS 44%. Early failures occurred in 26% of patients. In subset analysis, the best outcomes were seen in patients with ALK$^-$ ALCL with a 5-year OS of 70% and a PFS of 61%; AITL, OS 52%, PFS 49%; PTCL-nos, OS 47%, PFS 38%; and EATL, OS 48%, DFS 38% (Figure 58.1). Female gender and ALCL histology had positive prognostic value, and IPI had a predictive value for OS in AITL and for PFS in AITL and PTCL-nos. Bone marrow involvement and increasing age were negative prognostic factors.

Several other centers have reported similar studies, as detailed in Table 58.3. In the various groups, 41–73% of the PTCL patients were able to maintain eligibility for, and receive, autoHCT [46–50]. The remaining patients were taken off study owing to progressive or unresponsive disease, inability to mobilize sufficient stem cells, or comorbidities that prohibited autoHCT. Follow-up was typically 3–5 years, with OS ranging from 34 to 73% and PFS from 30 to 53%. The best results were from studies including ALCL patients [45,51]. The Korean cohort [49] included 25% of patients with NK/T-cell lymphoma and resulted in 5-year OS and EFS of 57 and 55%, respectively The induction regimens varied between studies, so it is difficult to make specific recommendations. The TRM was below 5% for all, which is reasonable in this relatively young and healthy population of patients. Most studies used chemotherapy-based conditioning and all excluded patients with CNS involvement, and also leukemic variants of PTCL and ATLL.

These studies evaluate the efficacy of autoHCT as consolidation therapy for first remission and compar with published data for chemotherapy alone in PTCL. A large population-based study from Sweden has analyzed the outcomes of over 755 patients treated over a 9-year period, including the patients from the Nordic Lymphoma study group (discussed previously [45]). In a subgroup analysis of 252 transplant eligible patients, the OS and PFS were significantly higher in the 128 patients transplanted in CR1 vs. the 124 who did not receive an autoHCT in CR1 [52]. A meta-analysis of 21 studies evaluating the effects of high dose therapy and autoHCT as first-line treatment in PTCL showed a trend towards improved outcomes compared to non-transplant therapies alone [53]; but there was not sufficient data to make firm conclusions. In these studies, a significant fraction of patients failed initial therapy prior to receiving autoHCT, underscoring the need for more aggressive and targeted therapies to improve initial response rate and reduce the number of early relapses. Late treatment failure patterns support the need to define better those patients at risk for late relapse through biomarker and minimal residual disease (MRD) evaluation. This could define a subset of patients who would benefit from maintenance therapy.

Allogeneic HCT for PTCL

Allogeneic HCT (alloHCT) has been used extensively to salvage patients with NHL and is generally considered to be curative therapy as it provides long-term remission with eventual plateaus in OS and PFS. However, alloHCT is associated with a high risk of complications related to continued immunosuppression, graft-versus-host

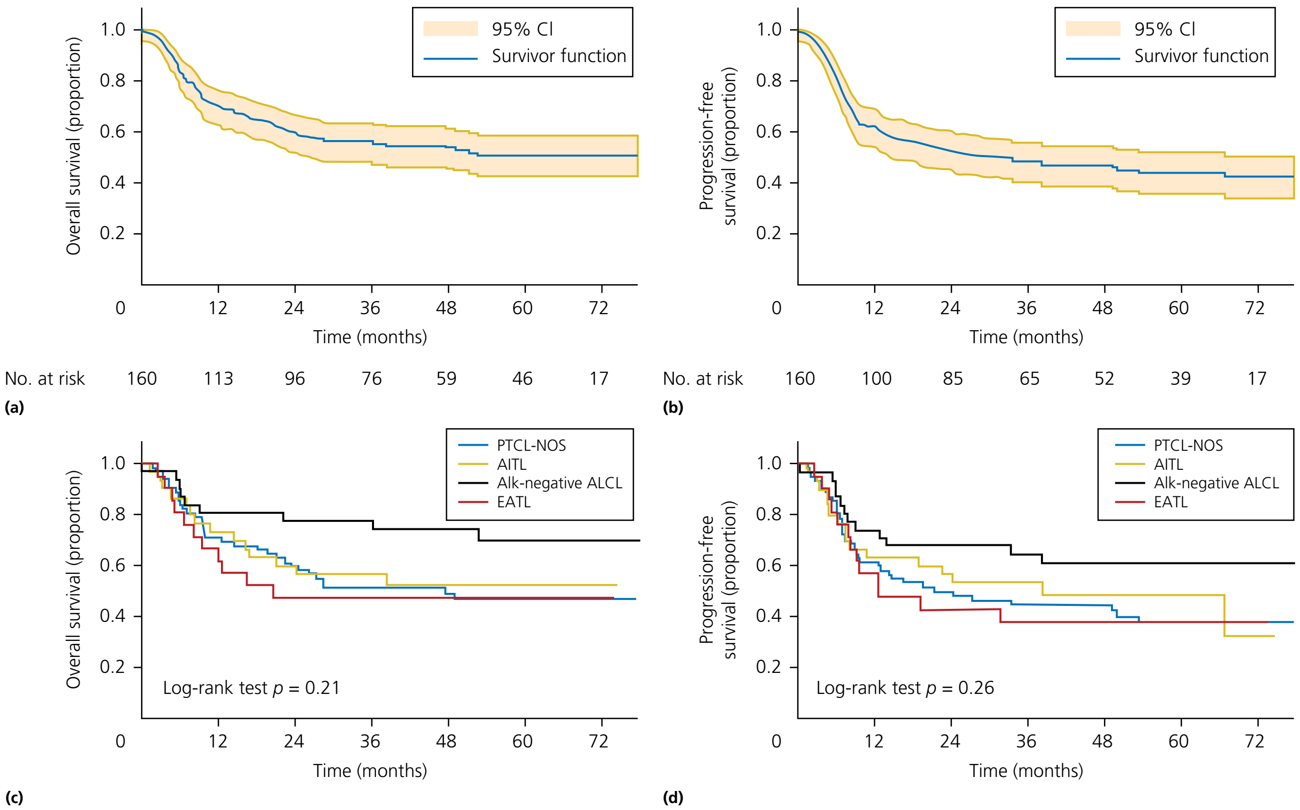

Figure 58.1 Kaplan–Meier estimates of (a) overall survival (OS) and (b) progression-free survival (PFS) for the entire NLG-T-01 cohort and (c) OS and (d) PFS for the four largest histologic subtypes. PTCL-NOS, peripheral T cell lymphoma, not otherwise specified; Alk-negative ALCL, anaplastic lymphoma kinase-negative anaplastic large-cell lymphoma; AITL, angioimmunoblastic T-cell lymphoma; EATL, enteropathy-associated T-cell lymphoma. disease (GVHD), and the long-term toxicities of conditioning regimens. The indications for this therapy are highly dependent on the availability of a donor, comorbid conditions of the patient, and previous treatments. The chance of cure or long-term remission has to be weighed against the risk of morbidity and mortality associated with the transplant procedure. For PTCL, the rationale for allogeneic transplants has been borrowed from the paradigm of treating aggressive- and intermediate-grade B-cell lymphomas with the intent of invoking a graft-versus-lymphoma (GVL) effect to provide long-term disease control. AlloHCT has been used in the setting of relapsed or refractory T-cell NHL, although increasingly transplant physicians are using this modality in the upfront setting for particularly aggressive histologies such as the γ/δ T-cell lymphomas and extra-nasal NK/T-cell lymphomas [54].

A French study has reported on the feasibility and toxicity of upfront alloHCT in 49 newly diagnosed PTCL patients. Forty-two patients had an HLA-matched donor, but only 29 proceeded to transplant after achieving a remission with CHOP. For transplanted patients the 1- and 2-year OS was 76% and 72%, respectively. TRM after 1 year was 8%. Of note, the PFS of the patients who did not undergo a transplant was less than 30% [55]. Most other published studies describe outcomes for treatment of relapsed disease. There is one prospective phase II study of 17 PTCL patients with relapsed disease reported by Corradini et al. [56]. All patients received similar debulking chemotherapy with cisplatin, dexamethasone, and cytarabine for 4–6 cycles and underwent reduced-intensity allogeneic transplant following conditioning with fludarabine, thioTEPA (*N*-triethylenethiophosphoramide), and cyclophosphamide. This study was also the first to report on the use of reduced-intensity conditioning (RIC) to reduce high TRM (previously reported at ~30%). With this particular approach, after a median follow-up of 28 months, the NRM was only 6% and the 3-year OS and DFS were 81 and 62%, respectively. This study established that RIC could be used in PTCL with good long-term outcomes implicating a graft-versus-T-cell lymphoma effect. The patients in this study were heavily pretreated, including 8/17 patients with a prior autoHCT; however, 15/17 were chemosensitive, indicating that the adverse outcomes associated with T-cell lymphomas can be overcome by alloHCT, at least in chemosensitive patients.

All remaining studies are retrospective and consist of patients with non-uniform histologies, conditioning regimens, and GVHD prophylaxis. As these diseases are rare, initial reports consisted of small case series, but in the last 10 years international institutions and lymphoma groups have made a concentrated effort to describe the experience of allogeneic stem cell transplantation in PTCL. AlloHCT studies for PTCL are listed in Table 58.4. Most studies are focused on the common nodal histologic subtypes of PTCL, namely PTCL-nos, AITL, and ALCL, and exclude CTCL, HTLV-1-associated ATLL, and patients with CNS involvement. The role of transplantation in ATLL is described elsewhere (Chapter 69).

The largest PTCL alloHCT study to date included 77 patients from multiple centers in France and was reported by Le Gouill et al. [57]. This study investigated differences in the common histologic subtypes of PTCL in the context of allogeneic stem cell transplant. All patients had relapsed disease and about 25% of them had failed a prior transplant, indicating the heavily pretreated

nature of the population. The histologic distribution was as follows: 27 ALCL, 27 PTCL-nos, 11 AITL, and 12 others including aggressive histologies; 77% of the patients had chemosensitive disease at the time of transplant and 67% received ablative conditioning regimens. TRM was high at 33%, and the 5-year OS and DFS were 57 and 53%, respectively. This is the only study demonstrating differences in outcomes based on histology. At 5 years, OS and PFS were 80 and 80% for AITL, 63 and 58% for PTCL-nos, 55 and 48% for ALCL, and 33% for other histologies (Figure 58.2). Both the OS and PFS curves reached a plateau after 20 months. Grade III and IV acute GVHD and chemoresistant disease were negative prognostic factors by multivariate analysis. The 5-year OS of 29% for chemoresistant patients is encouraging and supports a GVL effect.

Most published studies have reported similar numbers at 3–5 years of follow-up, with OS between 50 and 70% and PFS up to 60%, with a plateau in relapse incidence within the first 2 years. Chemosensitive disease at the time of transplant results in better OS and PFS [39,57–59], indicating that achievement of disease control before allogeneic transplant is crucial to outcome. In one of the larger studies of 52 PTCL patients, Dodero et al. reported superior 5-year relapse for patients allografted in CR compared with PR (24% vs. 54%), and for those with chemosensitive compared with refractory disease (40% vs. 77%) [58]. From a City of Hope study, the 5-year OS for patients in CR/PR compared with those with active disease was 72.9% versus 43.2% [60].

The effect of conditioning regimen is unclear, but there has been an increasing shift towards RIC in recent years due to the high TRM reported in earlier studies. TRM after alloHCT for PTCL has been reported to be as high as 30%, likely due to advanced-stage disease and poor performance status. Several centers have reported on the results of RIC [61,62] and there appears to be a decrease in TRM to around 19–20%. A study from City of Hope compared outcomes for RIC and fully ablative conditioning and found no differences in OS and DFS [60].

The Memorial Sloan Kettering Cancer center used T-cell depletion in 47 patients, resulting in a 25% incidence of chronic GVHD (compared with 60% and above in other series) and a TRM of 18% at 45 months [63]. They also examined pre-transplant Ki-67 immunohistochemistry as a biological marker in PTCL and found that Ki-67 nuclear expression in ≤25% cells, indicating a more indolent histology, correlated with better OS. Differences in OS and PFS for various histologies were reported for the 115 patients in the study by Le Gouill et al. mentioned above. The City of Hope series [60,62] compared CTCL and PTCL histologies and found similar outcomes for allogeneic transplants in the two groups. The EBMT Registry reported outcomes for AITL alone [39], with a 3-year OS of 64% and PFS of 53%, similar to those seen in other studies. Jacobsen et al. reported no difference in outcomes when histologies were stratified as nodal versus extranodal [64].The series from Japan focused on NK/T-cell lymphoma, based on its high prevalence in Japan, and reported inferior 2-year OS and PFS of 30–40% compared with 70% for PTCL from the same registry [59]. Nonetheless, patients undergoing either autoHCT or alloHCT for NK/T-cell lymphoma showed better outcomes than those without HCT [59,65].

PTCL, peripheral T-cell lymphoma; AITL, angioimmunoblastic T-cell lymphoma; ALCL, anaplastic large-cell lymphoma; other histopathologic subtypes are classified as “other.” Source: Le Gouill et al. 2008 [57]. Reproduced with permission of the American Society of Clinical Oncology.

The use of donor lymphocyte infusion (DLI) to induce remission for relapsed disease after allogeneic transplant is considered validation of a graft-versus-disease effect and there are reports in the literature documenting response to DLI for PTCL. The largest experience is from Dodero et al., where 8/12 patients with documented relapse responded to DLI and achieved a state of remission [58]. There were two patients in the Le Gouill series, two in the Corradini series [56], two in the Hamadani series [66], and one of two in the Goldberg series [63] who responded to DLI after disease relapse and had long remissions.

In conclusion, the use of alloHCT, at least in some of the common nodal histologies of PTCL, can provide long-term disease control for patients with chemosensitive disease, with most relapses occurring within the first 2 years. The risk of acute and chronic GVHD remains high, but TRM can be reduced using RIC to minimize regimen-related toxicities. A GVL effect is implicated by the success of RIC regimens and use of post-transplantation DLI to induce remission. However, disease chemosensitivity and optimal disease control are crucial for the best outcomes with this modality. The use of alloHCT in the upfront setting is still being explored and early data is encouraging. Since most relapses occur within the first 2 years after transplant, consideration should be given to maintenance therapies using targeted agents to reduce residual disease and improve outcomes following allogeneic transplantation for PTCL.

HCT for cutaneous T-cell lymphoma (CTCL)

Autologous HCT

For chemosensitive relapsed aggressive lymphomas, autoHCT is the standard of care. CTCL outcomes for this approach have paralleled those of other low-grade lymphomas, resulting in frequent relapses. Even though data are limited, a few small series have shown high response rates, but with early relapses, typically within a year (Table 58.5). These series reports of up to 10 patients indicate that high-dose therapy and TBI-based regimens can be delivered to CTCL patients without an increased incidence of transplant-related complications. T-cell depletion or CD34 selection do not appear to improve relapse incidence [67–73]. The use of autoHCT has not shown promising results in the relapsed setting of advanced CTCL, due mainly to the inherent chemoresistance of these tumor types.

Allogeneic HCT

In an attempt to improve the outcomes of high-dose therapy and provide better disease control, alloHCT has been performed in select patients with advanced disease, invoking the GVL effect. Owing to the general immunosuppressive state and the broken skin

barrier, infectious complications remain a major challenge in the management of CTCL patients. Even though early studies were small and retrospective, complication rates were acceptable, and supported an alloHCT approach [74–81].

To date there are approximately 30 articles in PubMed concerning the use of allogeneic transplant in mycosis fungoides or Sézary syndrome. Earlier studies were case reports of 1–3 patients with considerable heterogeneity in disease status, source of stem cells, conditioning regimens, and so on. These studies indicate that in spite of a broken skin barrier and a depressed immune system, allogeneic transplantation can be performed in CTCL patients with no apparent disease-specific complications. Despite the salvage setting, long-term disease control and survival can be demonstrated based on clearance of clinical symptoms and also molecular evidence of disease by TCR gene rearrangements [77–79,82–85] (Figure 58.3). GVL effects are evident from the successful use of RIC regimens, remission of relapse after withdrawal of immunosuppression and donor lymphocyte infusions [79], and an association of disease remission with GVHD [83]. A summary of these case reports is presented in Table 58.6.

With advances in the field of allogeneic transplants, there are now data regarding the use of cord blood as a stem-cell source for these patients [86,87]. A review of these cases in detail indicates that an allogeneic transplant can achieve a CR even in the most refractory cases, as shown in Figure 58.4, and RIC appears to be just as effective and less toxic. There may be increased skin toxicity and flaring associated with TBI-containing regimens. Disease recurrence in the skin can occur after alloHCT, but seems to respond well to adjustment of immunosuppression, DLI infusion, or mild treatments for the skin. There appear to be few blood or systemic recurrences. The numbers are too small to conclude whether recurrences are more common after RIC as opposed to fully ablative conditioning, but there seems to be a trend among physicians towards the use of RIC regimens.

There is at least one reported case of autoHCT followed by alloHCT from a human leukocyte antigen (HLA)-matched sibling for a CD8$^+$ mycosis fungoides patient with tumor stage disease and blood involvement, although it was not performed in a planned tandem fashion [88]. The patient was conditioned with alemtuzumab, fludarabine, and cyclophosphamide, with resolution of disease in the lungs and skin by day 17. A recurrence at day 18 was treated with withdrawal of immunosuppression with good results, although the patient died from sepsis at day 256.

Based on these case reports, several transplant centers have performed retrospective database analyses for CTCL patients who have undergone allogeneic transplantation, in an attempt to identify factors that may refine the use of alloHCT in the

management of these diseases. To date there have been no prospective studies on this topic. The series are focused on mycosis fungoides (MF) and Sézary syndrome (SS) and most physicians use these data to extrapolate for other types of CTCL. In the largest series of 129 patients with MF/SS, reported by the Center for International Blood and Marrow Transplant Research (CIBMTR), 64% of patients received RIC. The OS at 1 and 5 years was 54% and 32%, respectively, while the PFS at 1 and 5 years was 31% and 17%. The NRM at 1 and 5 years was 19% and 22%, respectively [89]. A retrospective analysis of 60 patients from the EBMT database included 36 patients with MF and 24 with SS; 44 patients received RIC conditioning and 25 underwent T-cell depletion. The OS in this series was 54% at 3 years. RIC yielded decreased NRM without increased relapse, resulting in improved OS, whereas T-cell depletion increased the relapse risk. DLI was used successfully to treat relapsed disease [90]. A meta-analysis of 39 cases of advanced MF/SS confirmed that at 5 years, alloHCT resulted in a better outcome (OS 80%, *n* = 20) compared with autoHCT (OS 23%, *n* = 19) [80]. The incidence of GVHD was reported to be as high as 90%. Patients with SS also showed encouraging results from alloHCT although they have rarely been reported. The results of alloHCT for dedicated CTCL series are summarized in Table 58.6, including a series that reports a subanalysis of outcomes for CTCL/MF/SS patients within a larger study of mature T-cell NHL [60].

Conclusion and future directions

The recent approval of targeted therapies for PTCL and CTCL is changing the landscape of these diseases. For patients with relapsed refractory NK/T-cell NHL, single-agent treatment with pralatrexate [91], vorinostat [92], romidepsin [93], or brentuximab vedotin [42] can serve as a bridge therapy prior to transplant, which remains the best option for long-term cure of these patients. With ongoing trials of novel agents singly and in combination, it is becoming

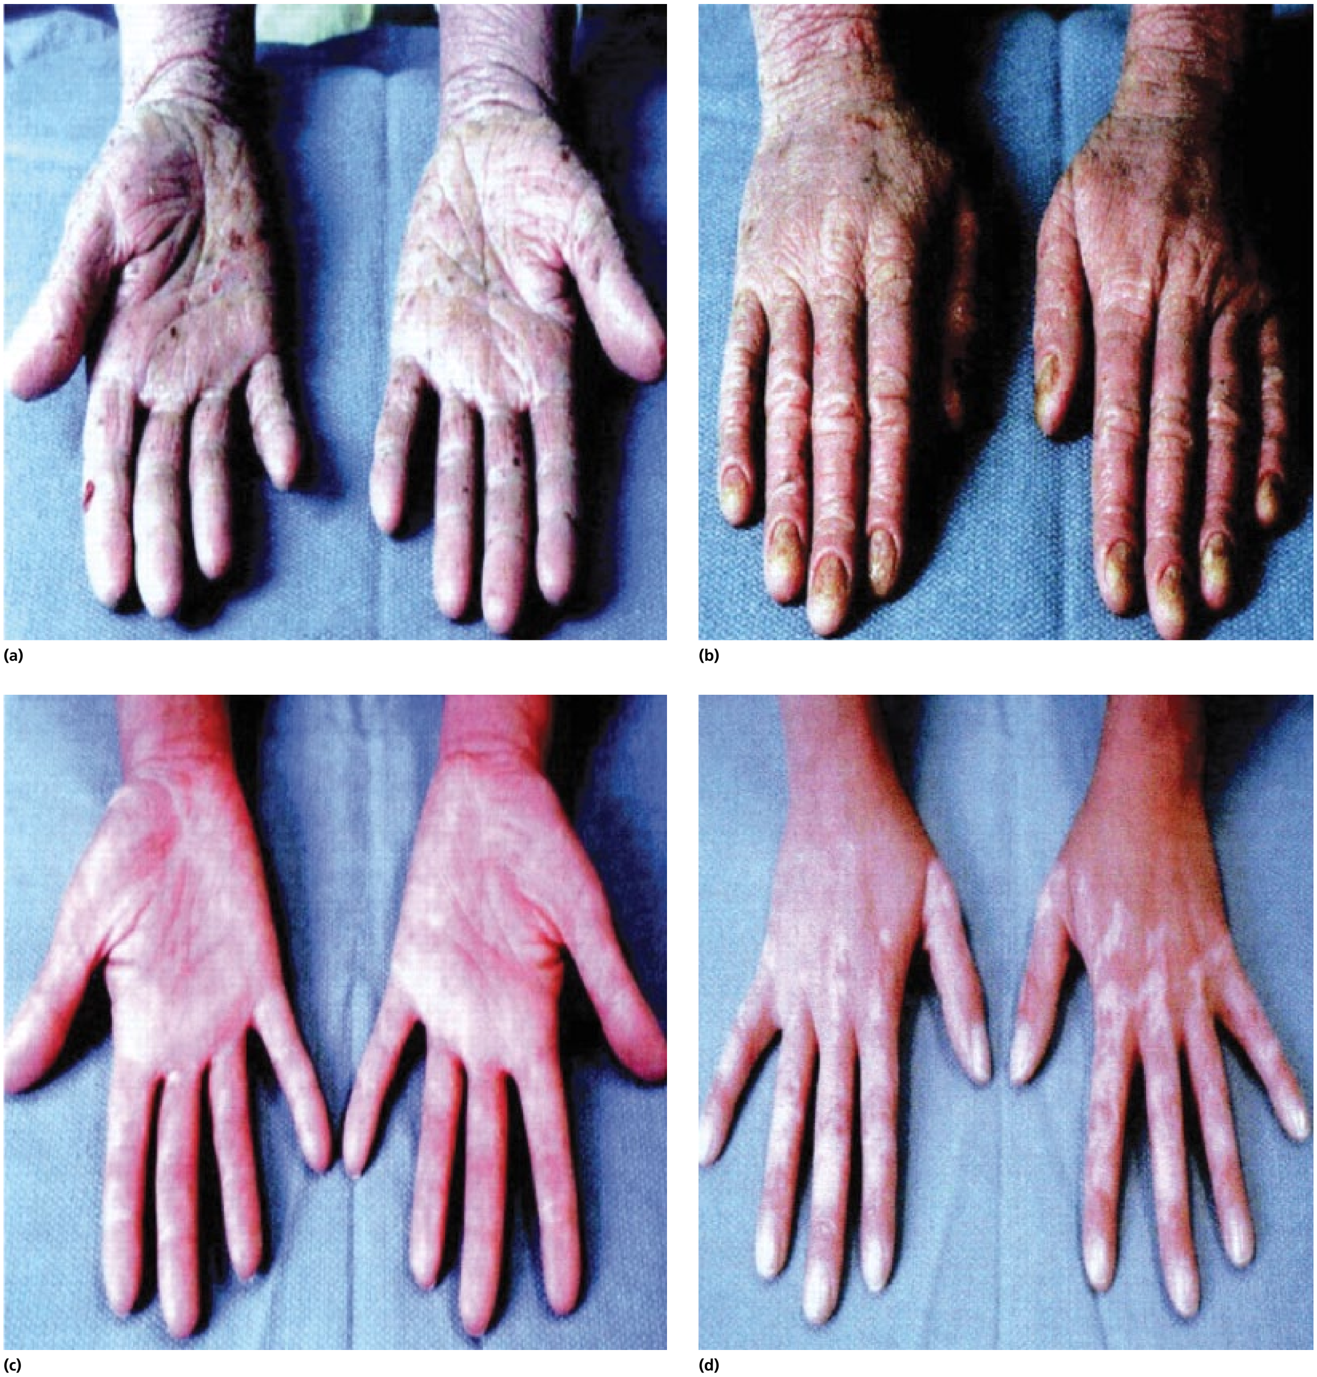

Figure 58.4 Patient with Sézary syndrome with generalized erythroderma and circulating (Sézary) cells. (a, b) Before alloHCT, the hands are affected with fissuring, cracking, and nail destruction. increasingly possible to depart from the B-cell lymphoma paradigm of toxic multiagent chemotherapy. The future will focus on more disease-specific, low-toxicity agents to treat NK/T-cell NHL and its various subtypes, in both the upfront and relapsed settings, to overcome the inherent chemoresistance of these tumors. We also expect that in time, novel agents will be approved for use in conditioning regimens and be considered for maintenance therapy in patients harboring residual disease post-transplantation.

CHAPTER 59

Hematopoietic Cell Transplantation for Chronic Lymphocytic Leukemia

Aaron C. Logan[1] **and David B. Miklos**[2]
[1] University of California, San Francisco, CA, USA
[2] Stanford University, Stanford, CA, USA

Introduction

Chronic lymphocytic leukemia (CLL) is the most common leukemia in adults, occurring in roughly 1 of 200 individuals surviving into their seventh decade. In spite of significant progress, CLL remains an incurable malignancy with conventional chemo-immunotherapy. Given the variable clinical course that patients experience, management of CLL has required the development of robust prognostic algorithms to determine which patients require therapy and, more specifically, which may benefit from aggressive therapies including hematopoietic cell transplantation (HCT). Additionally, treatment and transplant approaches suitable for patients with comorbidities have become increasingly important. Promising developments in the management of CLL that have recently emerged include the advent of small molecular inhibitors of B-cell receptor (BCR) and other signaling pathways, and it is probable these therapies ultimately will alter the landscape for management of CLL. Additionally, manipulated cell therapies such as chimeric antigen receptor (CAR)-expressing T cells hold the promise of targeting cell-mediated immunity for long-term disease control. At present, however, allogeneic HCT remains the only well-supported approach for achieving long-term disease control in high-risk CLL. Approximately 50% of high-risk CLL patients undergoing reduced-intensity conditioning (RIC) allogeneic HCT achieve durable complete remissions lasting 5 years or longer – indeed, many of these patients are likely cured. Such results will remain the benchmark for success for future therapeutic advances in the management of CLL.

Epidemiology

United States registry data from the Surveillance Epidemiology and End Results (SEER) program of the National Cancer Institute estimate that just over 16,000 men and women are diagnosed with CLL annually [1]. The per-capita incidence of CLL appears to be relatively stable (roughly 4.5–5 cases per 100,000), which contrasts with a documented increase in the incidence of non-Hodgkin lymphomas in general since the 1970s and 1980s (roughly 11 per 100,000 in 1975 up to 20.2 per 100,000 in 2009). The median age at diagnosis of CLL is 72 years, with roughly one-third of patients diagnosed being under 65 years of age. Roughly 10% are under 55 years of age at diagnosis, and less than 2% are younger than 45 years of age. Thus, although the relative incidence in young patients under the age of 65 years is low, the high incidence of CLL leads to a substantial population of transplant-eligible patients in need of curative therapy.

Etiology

In most, if not all, cases of CLL, the malignant clone may pass through a premalignant phase of accumulation termed monoclonal B-cell lymphocytosis (MBL) [2]. The rate of progression from MBL to CLL appears to be low, however, since 3–6% of adults with normal blood counts have detectable $CD19^+CD5^+CD23^+$ CLL-phenotype MBL. The incidence of MBL is likely 100 or more times higher than that of CLL, suggesting that monoclonal proliferation of B cells is only rarely associated with transition to malignancy in the form of CLL, with a roughly 1.1–1.4% annual risk of progression [3].

CLL is characterized by the progressive accumulation of morphologically mature-appearing small B lymphocytes, but their immature immunophenotype ($CD19^+CD5^+CD23^+$) and heterogeneous immunoglobulin heavy chain (IGH) rearrangements have not supported a unifying etiology thus far. Patients with CLL cells bearing somatically hypermutated (SHM) IGH loci, which suggests antigen-induced maturation in the germinal center, experience dramatically different clinical courses compared with those in whom IGH rearrangements lack SHM. This suggests that CLL may derive from two different etiologic pathways. In general, however, the CLL cells observable in the peripheral blood and bone marrow of patients are non-proliferative cells arrested in G0/G1, but are resistant to apoptosis. CLL cells overexpress the anti-apoptotic protein BCL2, suggesting that this leads to accumulation of cells otherwise destined to undergo programmed cell death [4]. Necessarily, there is some element of proliferative drive leading to the markedly elevated absolute lymphocyte counts seen in some patients with CLL – in some cases higher than 200,000–500,000/µL. The molecular drivers underpinning the proliferative drive in CLL remain to be better elucidated.

Although many acute leukemias and other hematolymphoid malignancies arise in association with chromosomal translocations leading, generally, to the dysregulated expression of proto-oncogenes, CLL has not demonstrated an association with chromosomal translocations. Rather, the primary pattern appears to be loss of cell cycle regulators, including proteins such as Ataxia Telangiectasia Mutated (ATM) at 11q22-23 and tumor suppressor p53 at 17p13, but also micro-RNAs (miRNAs) that may serve regulatory roles [5]. The most

common cytogenetic abnormality associated with CLL is a deletion at 13q14.3 that develops in more than 50% of cases followed longitudinally [6]. Two miRNAs, *MIRN15A* and *MIRN16-1*, cluster within 200kb at 13q14.3 [7]. They are ubiquitously expressed as non-coding RNAs with highest expression in normal CD5$^+$ lymphocytes. The majority of CLL patients have decreased *MIRN15A* and *MIRN16-1* expression that correlates with loss of heterozygosity (LOH) in 68% of informative cases.

Insights from studies using recently developed genomic technologies, including gene expression arrays and next-generation sequencing, have revealed extensive molecular heterogeneity in CLL. In 2011, several large-scale whole genome sequencing (WGS) and/or whole exome sequencing (WES) efforts were reported, revealing consistent identification of frequently mutated genes in CLL [8–10]. Puente et al. performed WGS on four patients with CLL to identify candidate mutated genes, which were then analyzed in 363 additional patients. Recurrent mutations in *NOTCH1*, *XPO1*, *MYD88*, and *KLHL6*, with the first two clustering with cases of IGH unmutated CLL and the latter two clustering in patients with IGH mutated CLL [8]. Quesada et al. completed WES on 105 patients with CLL, identifying 78 genes with predictable functional alteration and occurrence in at least two patient tumors [10]. Among the most commonly mutated proteins was SF3B1, a subunit of the spliceosome, mutation of which was associated with poor overall survival [10]. Using WES and WGS on CLL cells, Wang et al. studied 91 individuals and identified nine genes mutated with significant frequency in CLL patients, including *TP53*, *ATM*, *MYD88*, *NOTCH1*, *SF3B1*, *ZMYM3*, *MAPK1*, *FBXW7*, and *DDX3X* [9]. These nine genes implicated five core signaling pathways in the pathogenesis of CLL, including DNA damage and cell cycle control, Notch signaling, inflammatory pathways, Wnt signaling, and RNA splicing and processing, thus providing new directions for the development of targeted therapies. Schuh et al. used WGS to demonstrate intratumoral heterogeneity in the form of subclonal populations in three IGH unmutated CLL patients sampled at five time points for 7 years [11]. Increasingly aggressive clones bearing increasing mutational burdens appear to be selected for with successive rounds of treatment, suggesting that this analytic approach will become vital for targeting emergent, treatment-resistant clones.

Clinical presentation, diagnosis, and staging

CLL is frequently diagnosed in asymptomatic individuals in whom routine blood count testing reveals absolute lymphocytosis. Some patients, however, present with profound lymphadenopathy or constitutional symptoms associated with rapidly expanding malignant cells, i.e., fever, night sweats, and weight loss. Other patients present with fatigue secondary to anemia resulting from either bone marrow infiltration with CLL cells or paraneoplastic autoimmune hemolytic anemia.

The diagnosis of CLL is suggested by peripheral blood lymphocytosis and confirmed by flow cytometry of blood or marrow revealing a clonal B-cell population expressing mature B-cell marker CD19, low-level CD20, and high-level CD5 and CD23 [12,13]. In the WHO classification, CLL is always a neoplastic B-cell disease, while the entity previously referred to as T-CLL is now called T-cell prolymphocytic leukemia (T-PLL) [14]. CLL cells expresses low-level immunoglobulin with evidence of either lambda or kappa light-chain restriction. The National Cancer Institute – Working Group (NCI-WG) CLL diagnostic criteria [15] were established in 1988, with revisions in 1996 and 2008, and include [15,16]:

1. A lymphocyte count >5 × 10^9/L with small mature lymphocytes in the peripheral blood for more than 1 month.
2. Immunophenotype as detected by flow cytometry showing:
   - **a** light chain restriction;
   - **b** coexpression of CD19 and CD5 together with CD23 expression;
   - **c** low expression of surface immunoglobulin and the absence or low expression of CD79b.

A bone marrow biopsy is not required for diagnosis, but is recommended before initiating therapy [16]. A bone marrow biopsy, however, is required to assess a complete remission and is often useful when evaluating factors that may contribute to cytopenias including autoimmune responses, leukemia infiltration, or therapy-related causes. Computed tomography (CT) and/or positron emission tomography (PET) scans are not required for diagnosis, and staging relies on physical examination and blood counts only. CT ± PET scans may be useful in select patients with clinically problematic lymphadenopathy.

Two staging systems for defining degree of CLL disease involvement have been validated, the modified Rai staging system [17,18] and the Binet staging system [19] (Table 59.1). Both systems signify advancing degrees of CLL involvement based on the presence of lymphadenopathy, hepatosplenomegaly, and degree of marrow compromise.

Table 59.1 Modified Rai and Binet staging systems for CLL

Stage	Findings	Median OS (months)
Rai [17,18]		
0	Lymphocytosis only	>120
I	Lymphocytosis + lymphadenopathy	95
II	Lymphocytosis + hepatosplenomegaly	72
III	Lymphocytosis + Hb <11g/dL	30
IV	Lymphocytosis + Plt <100 × 10^9/L	30
Binet [19][a]		
A	Hb >10g/dL, Plt >100 × 10^9/L, <3 enlarged areas	>120
B	Hb >10g/dL, Plt >100 × 10^9/L, ≥3 enlarged areas	61
C	Hb <10g/dL or Plt <100 × 10^9/L	32

Hb, hemoglobin; Plt = platelets.

[a] Binet areas include cervical, axillary, or inguinal (each unilateral or bilateral), spleen and liver, with number of enlarged areas ranging from 0 to 5.

Prognostic markers

The natural history of CLL is heterogeneous, with survival ranging from months to decades, and overall survival is grossly predicted by the Binet and Rai staging systems (Table 59.1). Patients with low-risk disease have a median survival of 15 years, patients with intermediate-risk disease survive 5–7 years, and patients with high-risk disease have a life expectancy of less than 3–4 years [20]. Amongst low-risk patients, 50% ultimately require treatment and over 25% die of causes related to CLL, demonstrating the need to use additional methods for prognosticating patient outcomes [21,22]. Additionally, these clinical staging systems do not predict an individual's rate of clinical progression when diagnosed with early-stage disease, or the likelihood of response to treatment in a patient with advanced-stage disease.

Markers of CLL tumor burden

Lymphocyte doubling time and the bone marrow infiltration pattern are easily assessable and have prognostic relevance in CLL. A lymphocyte doubling time of >12 months predicts long treatment-free survival and prolonged overall survival [23]. Bone marrow CLL histology demonstrating diffuse infiltration conveys a worse prognosis than nodular infiltrates [24]. Serologic measurements that correlate with tumor burden include β_2-microglobulin and soluble CD23. β_2-Microglobulin is an extracellular protein that associates with the α-chain of class I major histocompatibility complex (MHC), and high values predict poor responses to chemotherapy and shortened survival [25]. Elevated soluble CD23 at initial diagnosis also predicts early disease progression [26].

Cytogenetic prognostic markers

Approximately 80% of CLL patients have cytogenetic abnormalities detected by fluorescence in situ hybridization (FISH) [6]. These genomic abnormalities provide pathogenic insights as they identify candidate genes and have prognostic significance, as shown in Table 59.2. The median survival times for the 17p deletion, 11q deletion, 12q trisomy, normal karyotype, and 13q deletion groups were shown by Döhner et al.'s study to be 32, 79, 114, 111, and 133 months, respectively [6], and have been independently confirmed by other groups [27,28]. Interphase cytogenetic abnormalities, especially detection of 17p deletion and 11q deletion, have been confirmed as high-risk CLL features predicting shortened progression-free survival and overall survival for untreated CLL patients who receive combined fludarabine and rituximab [29] or fludarabine and cyclophosphamide treatment [30]. In these studies, high-risk cytogenetic features did not identify which patients respond to these initial therapies, but predicted who would experience disease progression more quickly and have shortened survival.

Detection of high-risk cytogenetic features could influence initial treatment decisions because CLL patients who have CLL with deletion of chromosome 17p respond poorly to fludarabine-based therapy, and may benefit from use of alemtuzumab [31–33]. Initial studies with the Bruton's tyrosine kinase (BTK) inhibitor ibrutinib (PCI-32765) also showed promising results with 17p deleted CLL [34]. Because cytogenetic markers have proven to be so powerful for prognosis in CLL, it is recommended that interphase cytogenetic assessment, including FISH analysis for chromosome 11 and 17 abnormalities, be performed on all CLL patients needing treatment, and it is imperative that these data be acquired for patients treated in clinical trials and those being considered for HCT [16]. Repeating cytogenetic and FISH studies upon relapse may reveal clonal evolution and acquisition of clinically relevant poor prognostic markers such as 17p deletion [35].

Table 59.2 CLL prognostic markers

Group [6]	Frequency (%)	Median OS (months)
FISH cytogenetics		
del 13q (heterozygous)	55	133
Normal karyotype	18	111
Trisomy 12	16	114
del 11q	13	79
del 17p	9	32
IGH mutation [40]		
Somatically mutated	44	152
Unmutated	56	79
V3–21	11	63
Zap-70 expression [45]		
<20%	50	NR
>20%	50	29
CD38 [47]		
<30%	58	293
>30%	42	109

FISH, fluorescence in situ hybridization; del, deletion; IGH, immunoglobulin heavy chain; NR, not reached; OS, overall survival.

IGH gene mutation status

One of the most useful prognostic indicators for CLL is the IGH gene mutation status [36,37]. CLL appears to arise from a stage of B-cell ontogeny bridging the point at which antigen-induced affinity maturation may occur in the germinal center. As such, SHM at the IGH locus may reveal important underpinnings of two subsets of CLL that appear to have very different natural histories – somatically mutated versus unmutated CLL. The IGH locus is considered unmutated when the V, D, and J segments remain >98% identical with germline IGH gene segments published by the International ImMunoGenetics (IMGT) Information System [38,39]. Approximately half of CLL patients possess clones with unmutated IGH genes, and these patients have relatively poor clinical outcomes with rapid disease progression, shortened time to treatment, and shortened overall survival. In a study of 300 CLL patients stratified by IGH mutation status, the median survival times were 79 months for the IGH unmutated group and nearly double that at 152 months for the mutated group (Table 59.2) [40]. Interestingly, a prospective analysis of 64 CLL patients over a minimum period of 3 years identified 11 patients undergoing cytogenetic clonal evolution, and all 11 had unmutated IGH gene status, suggesting that unmutated IGH CLL may have chromosome instability [35]. We recommend obtaining the IGH mutation status on all CLL patients, both for prognostic reasons and for potential use as a molecular minimal residual disease (MRD) marker (discussed below). Another benefit to sequencing IGH is the possibility of revealing high-risk V segment usage, such as V3–21, which conveys a poor prognosis in spite of SHM [41,42].

CD38 and ZAP-70 expression

IGH mutational status has historically been difficult to determine for some institutions, but the availability of this assay has recently improved and should be available to most patients. Cell surface markers assessable by flow cytometry have been evaluated for their correlation with IGH mutation status to allow prognostication when IGH mutation status was unavailable. CD38 expression on CLL cells was the first of these markers demonstrated to correlate with IGH mutation status – higher level CD38 (>30%) is more frequently found on IGH unmutated CLL and correlates with a poor prognosis [36]. CD38 expression is dynamic and may correlate directly with activation and proliferative status; however, there is no established role for serial assessment of CD38 expression [43]. Gene expression profiling subsequently demonstrated a close association between expression of zeta-associated protein (ZAP-70) and IGH unmutated CLL [44]. ZAP-70 is highly expressed in natural killer (NK) and T cells whereas normal B cells have low or no ZAP-70 expression. ZAP-70 expression on >20% of CLL phenotype cells is associated with worse prognosis and there is a strong correlation between IGH unmutated status and ZAP-70 positivity. Additional studies have shown, however, that approximately 10–30% of CLL clones are discordant between ZAP-70 and IGH mutation status [40,42,45–47]. Together, these data suggest that a prognostic model for CLL can be based on either genomic alterations and ZAP-70 expression or IGH mutation status, high-risk genomic aberrations, and canonical high-risk V-segment usage (e.g., V3–21) [42]. This need for multiple independent prognostic predictors suggests again that CLL is a heterogeneous disease with multiple pathogenic mechanisms.

Response criteria

Assessment of response includes a careful physical examination and evaluation of blood and marrow. According to the revised NCI-WG guidelines, a complete response requires a normal physical examination, lymphocytosis ≤ 5×10^9/L, the absence of clonal lymphocytes, hemoglobin >11g/dL, and platelets >100×10^9/L. Patients with residual CLL cells by conventional flow cytometry or immunohistochemistry are defined as having partial response (PR) [16].

Minimal residual disease – methods for monitoring depth of treatment response

Chronic lymphocytic leukemia is readily amenable to detection and quantification of MRD using either multiparameter flow cytometry (MPFC) or molecular methods based on detecting clonal immunoglobulin gene rearrangements specific to the malignant clone using allele-specific oligonucleotide polymerase chain reaction (ASO-PCR)- or high-throughput sequencing (HTS)-based approaches. These methods have become increasingly relevant as the efficacy of therapy has improved and a larger proportion of patients are achieving deep remissions. It remains equally important, however, that as the ability to identify high-risk CLL patients has improved, to develop methods to monitor early loss of response to therapy in patients who ultimately fare poorly with successive relapses.

The European Research Initiative in CLL (ERIC) group has mounted an impressive effort to establish an internationally harmonized method for quantifying CLL MRD using four- or six-color MPFC [48,49]. In 2007, this group identified four-color antibody panels consisting of CD5/CD19 with CD20/38, CD81/22, and CD79b/CD43 that performed well across different laboratories with >95% accuracy and 95% concordance with ASO-PCR when disease burden was above 1:10,000 [48]. In an attempt both to simplify the standardized work flow for MPFC MRD detection and to provide the possibility of deeper sensitivity, the ERIC group subsequently demonstrated that a preliminary assessment using CD5/CD19/κ/λ was adequate for identifying samples with high probability of containing residual disease. The panel provided a 100% positive predictive value when samples contained more than 82% of B cells with CD5 expression and skewed light-chain ratio (κ:λ <0.05:1 or >32:1), which was adequate, but only qualitative, for about half of the 784 samples they evaluated from CLL patients during and after therapy [48]. The authors noted, however, that the expression of CD5 on regenerating B cells following allogeneic transplant may confound this analytic algorithm, which may be particularly relevant following HCT [49–51]. For samples in which CD5/CD19 and light-chain clonality were insufficient to identify residual disease, the group recommended analysis using six-color antibody panels consisting of CD5/CD19/CD20 with CD3/CD38/CD79b and CD81/CD22/CD43. This approach demonstrated 100% concordance with the previously standardized four-color panels using the same antigens, and because of the additional channels available with each assay on six-color cytometers, fewer tubes per patient need be analyzed, thus improving time efficiency. At least 50 events with the CLL immunophenotype are required to identify MRD confidently, thus necessitating the collection of a minimum of 500,000 leukocyte events on the cytometer for a 1:10,000 MRD detection threshold.

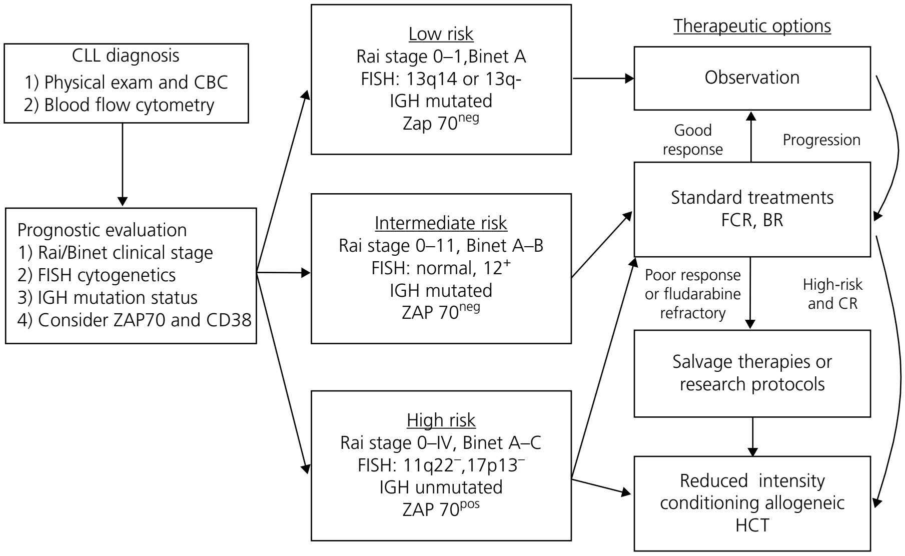
A frequently used alternative to immunophenotyping-based MRD detection is the use of molecular approaches for detection and quantification of CLL-specific IGH rearrangements in genomic DNA isolated from blood or bone marrow samples. Most of this work has been achieved using ASO-PCR, in which one or more patient-specific ££PCR primers and quantitative PCR probe are generated to make patient-specific assays [52,53]. This approach, although offering improved sensitivity (1:100,000 routinely), is not available outside a small number of academic centers with the resources to maintain the expertise for patient-specific assay development and validation.

We recently demonstrated a method for MRD quantification in CLL using a platform comprised of consensus IGHV and IGHJ primers and next-generation sequencing. Using 454 pyrosequencing and BIOMED-2 primers [54,55], a pilot study of six post-transplant CLL patients demonstrated accurate MRD quantification to a threshold of 1:100,000, with good correlation with ASO-PCR [56]. This study also identified some of the bioinformatic hurdles that must be overcome for accurate disease quantification using a sequencing-based approach. In a larger study with 40 patients and using an Illumina HTS-based MRD quantification approach called Sequenta LymphoSIGHT, MRD was quantified in all patients using consensus primers with a detection threshold of 1:1,000,000 [57]. The greatest advantage of this approach is the ability to assay all CLL patients for MRD without generating allele-specific primers or probes, as is necessary for ASO-PCR. Added sensitivity through sequencing depth (e.g., 1:1,000,000 detection) is a feature not easily achievable with MPFC or ASO-PCR, the benefit of which remains to be determined in larger studies. We have demonstrated that the IGH sequence data generated for the purpose of MRD quantification in CLL can also be use to profile the immunoglobulin repertoire, which may have importance in the post-transplant setting for monitoring the effects of graft-versus-host disease (GVHD) and its treatment on B-cell reconstitution [58].

Initial CLL therapy

Although the comprehensive description of treatment options for CLL patients is beyond the scope of this chapter, Figure 59.1 shows a schema for CLL diagnosis, prognostic evaluation, and therapeutic options. For those with low-risk CLL (Rai stage 0–1/Binet A, 13q14 cytogenetics, and mutated IGH gene status), observation with clinical follow up every 3–6 months is usually acceptable. Symptomatic disease progression or intermediate-risk disease at diagnosis may be managed with standard therapy. For decades, the standard therapy was chlorambucil, but this approach is now primarily used in patients with comorbidities. Three randomized trials have demonstrated significantly higher complete response (CR) rates and longer progression-free survival (PFS) using fludarabine-based therapy compared with alkylator-based therapies [59–61]. A subsequent randomized trial demonstrated that fludarabine plus cyclophosphamide combined therapy is superior to single-agent fludarabine as initial therapy, providing improved overall response rate (ORR), CR, and PFS [62].

The addition of monoclonal antibodies directed at B-cell surface antigens further improves the therapeutic benefit of chemotherapy. Rituximab, a chimeric humanized mouse anti-human CD20 antibody, and alemtuzumab, a humanized rat anti-human CD52 antibody, are effective as single agents or in combination therapy. Combining purine analogs with an alkylating agent and rituximab [i.e., fludarabine, cyclophosphamide, and rituximab (FCR)] has been reported to provide overall response rates of 95% and complete response rates of 70% [63]. In addition, these combination regimens can achieve molecular remissions; however, higher response rates have not yet demonstrated improved overall survival, and most patients treated with FCR will eventually relapse.



CLL diagnosis
1) Physical exam and CBC
2) Blood flow cytometry
Prognostic evaluation
1) Rai/Binet clinical stage
2) FISH cytogenetics
3) IGH mutation status
4) Consider ZAP70 and CD38

Progression
Standard treatments
FCR, BR
Poor response or fludarabine refractory
High-risk and CR
Salvage therapies or research protocols
Reduced intensity conditioning allogeneic HCT

Figure 59.1 CLL diagnosis, prognostic evaluation, and treatment options. Risk-stratified CLL disease assessment guides treatment. High-risk patients are predicted by cytogenetic abnormalities 11q⁻ and 17p⁻, unmutated IGH gene status, and IGH V3–21 usage. High-risk patients follow a treatment course that begins with standard combination therapy to cytoreduce their disease, and once they achieve adequate disease control they should be considered for RIC allogeneic HCT.

A recent alternative to FCR favored by some for its improved tolerability is bendamustine with rituximab (BR). Although bendamustine originally acquired its US Food and Drug Administration (FDA) label for indolent NHL, it has proven to be useful in both front-line and salvage therapy in CLL. The German CLL Study Group performed a phase II trial using BR in front-line therapy and demonstrated an 88% overall response rate with 23% CR and 65% PR. Response rates were favorable in IGH unmutated and 11q deleted CLL, but only 38% of those with 17p deletions achieved a PR and none achieved a CR [64].

Clinical challenges in advanced and high-risk CLL

Although most patients with CLL are elderly and half of CLL patients may not require treatment, there is a substantial proportion of young patients diagnosed with CLL bearing high-risk features, including IGH unmutated status, 17p or 11q deletions, and/or high ZAP-70 expression. It is these patients for whom it is valuable to consider the role for HCT. Recommendations regarding the use of allogeneic HCT in first CR in specific circumstances, or at relapse, are likely to change over the coming years if preliminary results with targeted therapies are confirmed. Nevertheless, at present, allogeneic HCT remains the only known modality offering long-term disease-free survival to patients. It is important to have a framework within which to guide patients in treatment decisions involving HCT therapy. A reasonable part of discussion for patients with high-risk CLL is the rationale for allogeneic HCT instead of autologous HCT, as the latter is typically recommended for relapsed non-Hodgkin lymphomas, but currently has a limited role in the management of CLL.

Historical experience with autologous transplantation

High-dose chemotherapy with autologous HCT for CLL was explored in the 1980s–1990s, but this approach has not been compared with conventional chemo-immunotherapy or allogeneic HCT in randomized controlled trials. Nonetheless, clinical and molecular remissions have been reported using autologous HCT, including in patients with poor prognostic features [65,66], so these results may yet be instructive.

Relative to other hematologic malignancies, autologous HCT was introduced to CLL care relatively late, presumably due to concern that persistent CLL would contaminate the graft. To address this concern, the first clinical trial of autologous HCT for CLL employed in vitro “purging” of the bone marrow graft with anti-CD20, anti-CD10, and B5 monoclonal antibodies via complement-mediated cell lysis [67]. All 12 patients in this pilot study achieved timely hematologic reconstitution and 11 achieved clinical CR. Six of the 12 obtained molecular remissions by clonal IGH gene rearrangement PCR detection studies. Khouri et al. reported a similar 11-patient early feasibility study using total body irradiation (TBI) and cyclophosphamide (CY) conditioning with anti-CD19 immunomagnetic bone marrow graft purging [68]. Six patients achieved CR and five had no detectable MRD by IGH PCR analysis. In all, at least six single-center phase I or retrospective studies with fewer than 20 patients each investigated autologous HCT for CLL [69–74].

Subsequently, three phase II and three phase III studies of autologous HCT in CLL have been reported (Table 59.3). Of note, all of these trials were initiated prior to the availability of rituxumab, and the main impetus for these studies was the poor success of conventional treatment regimens at the time (chlorambucil alone, fludarabine alone, or fludarabine with an alkylator). The Dana-Farber Cancer Institute (DFCI) reported experience using autologous HCT with B-cell-depleted marrow after TBI/CY conditioning in 137 patients with high-risk CLL between 1989 and 1999 [75]. Patients in this trial were a mix of relapsed CLL and high-risk CLL immediately following front-line therapy. With a median follow-up of 6.5 years, the PFS was 30% and overall survival (OS) was 58%, notably without evidence of a survival plateau. A high rate of secondary neoplasms, including therapy-related myeloid neoplasia (12%), was observed [75].

The UK Medical Research Council (MRC) completed a trial in which 115 patients were deemed eligible for autologous transplantation

Table 59.3 Selected studies of autologous HCT for patients with CLL

Study	*n*	Median age (years)	Conditioning regimen	Graft Purge	NRM	CR	Minimal residual disease	PFS (median f/u)	OS (median f/u)	Second malignancy incidence (%)

after front-line fludarabine therapy from 1999 to 2004 [76]. Importantly, this trial identified a high rate of failed hematopoietic stem-cell mobilizations following fludarabine, with only 67% of patients collecting an adequate graft. With 65 patients ultimately undergoing TBI/CY or BCNU [1,3-bis(2-chloroethyl)-1-nitrosourea], etoposide, Ara-C (cytosine arabinoside), and melphalan (BEAM) conditioning with autologous CD34-selected (i.e., T- and B-cell depleted) peripheral blood progenitor cell (PBPC) transplant, the 5-year PFS was 51.5% with 77.5% OS. Complete remissions increased from 37% pre-HCT to 74% after HCT. Sixteen of 20 evaluable patients achieved MRD negativity as assessed by IGH PCR, and the presence of MRD after autologous HCT predicted subsequent relapse [76]. The rate of therapy-related myeloid neoplasia was similar to the DFCI study at 12.4%.

Lastly, the German CLL Study Group recently published data from their CLL3 trial in which autologous HCT was included as part of front-line therapy [77]. Between 1996 and 2002, a total of 131 patients received ex vivo B-cell-depleted autologous PBPC after induction chemotherapy [cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), prednisone, and prednisone (CHOP), fludarabine, or fludarabine with cyclophosphamide], followed by a dexamethasone (Dexa)-BEAM mobilization prior to stem-cell collection, followed by a TBI/CY preparative regimen. After a median follow-up of nearly 9 years, the median PFS and OS were 5.7 and 11.3 years, respectively. This trial retrospectively evaluated diagnostic samples from all patients with cytogenetic and IGH mutation studies and determined that those with 17p deletions [PFS hazard ratio (HR) 19.08, $p < 0.001$; OS HR 8.35, $p < 0.001$] and IGH unmutated status (PFS HR 3.35, $p < 0.001$; OS HR 3.11, $p = 0.006$) did poorly after autologous HCT. Molecular MRD was evaluated in 52 patients and although there was a median MRD reduction of >3 logs, few achieved MRD negativity. The risk of secondary malignancy in this trial was 19% at 10 years of follow-up. Within the above report, Dreger et al. also presented a retrospective comparison between the autologous HCT patients on the CLL3 trial and 126 patients receiving FCR on the CLL8 trial [78]; between 2002 and 2006, time to retreatment and OS did not differ between the two groups, suggesting no benefit for high-dose therapy in the rituximab era.

Three randomized trials involving autologous HCT for CLL have been conducted. From 2001 to 2007, the French CLL group conducted a trial in which 241 patients with advanced CLL (Binet B or C) received three cycles of mini-CHOP, then three cycles of fludarabine, and those who were in CR after these therapies were randomized to autologous HCT or observation [79]. Of 105 who achieved CR, 52 underwent autologous HCT and 53 were observed expectantly. The 3-year event-free survival (EFS) for the two groups was 79.8 and 35.5%, respectively, with similar OS rates above 95%. Patients who did not enter CR with the induction regimen were randomized to autologous HCT or fludarabine plus CY and, importantly, these two groups had similar 3-year EFS of roughly 45% without a difference in OS (~85% in both).

The EBMT Chronic Leukemia Working party randomized 223 patients with response to first- or second-line treatment to autologous HCT or observation [80]. In 112 autografted patients, the median EFS was 51.2 months with a 5-year EFS of 42%. In 111 patients managed expectantly, the median EFS was 24.4 months with a 5-year EFS of 24%. OS, however, was not significantly different at 85.5 and 84.3%, respectively. Of note, this trial included very few patients with 17p deletions and roughly 13% of patients had Binet A disease with progression. These lower risk features may account for the relatively high 5-year OS. This trial again identified a high rate of collection failures, with roughly 10% being unable to proceed to autograft due to inadequate stem-cell yield.

Recently, Brion et al. reported results from the GOELAMS LLC 98 trial, in which 86 patients received either six cycles of monthly CHOP, followed by CHOP maintenance every 3 months for six additional cycles for those achieving only PR, versus three cycles of monthly CHOP followed by CY mobilization of PBSC then a CD34 selected autograft following conditioning with TBI/CY [81]. Those in PR after collection were given a supplementary three cycles of fludarabine prior to the autograft. Although the PFS was longer with up-front autograft (53 months versus 22 months, $p < 0.0001$), there was no significant difference in median survival of ~105 months.

In summary, although autologous HCT provides benefit for disease control in patients receiving only chemotherapy without rituximab, it likely does not improve response rates in the rituximab era. The high rate of treatment-related MDS/AML after TBI-based preparative regimens (10% or higher) is a significant concern, and it remains unknown whether autologous HCT for CLL after chemotherapy-based conditioning would have a more favorable risk profile, but it is unlikely that such studies will be carried out, as the likelihood of improving PFS rates is low.

Allogeneic transplantation

Because autologous HCT fails to achieve a plateau in relapse and risk of death, and is associated with a high risk of secondary malignancy, allogeneic HCT has become generally strongly favored over high-dose chemotherapy with autologous HCT for patients with relapsed or high-risk CLL. The prevailing preference for allografting in CLL is based on the fact that CLL is a malignancy with a well-established responsiveness to graft-versus-leukemia (GVL) effects [75,82–85]. An important question, then, is whether conditioning intensity is important to convey adequate disease control, or it is sufficient to achieve adequate engraftment with RIC approaches and permit GVL effects to control the disease. Early experience with myeloablative allogeneic HCT for patients with CLL revealed GVL activity, but overall outcomes were unsatisfactory, owing to high non-relapse mortality (NRM) or treatment-related mortality (TRM), as discussed below, and RIC regimens have rapidly become the favored approach for allogeneic HCT.

Special donor considerations in allogeneic transplantation for CLL

Siblings have been noted to have clonal B-cell proliferations in 8–10% of CLL patients' families [86–88]. The overall risk for developing CLL is two to seven times higher for first-degree relatives than in the general population [89]. This has special significance in allogeneic HCT when siblings may be used as donors, and supports screening of HLA-identical siblings using peripheral blood flow cytometry to assess for CLL-phenotype monoclonal B-cell lymphocytosis ($CD19^+CD5^+CD23^+$). Identification of a clonal B-cell population in a prospective donor carries bioethical considerations, as discussed by Hardy et al. [90], and it is our practice instead to select a matched unrelated donor when possible. The basis for germline transmission of CLL risk remains to be better elucidated.

Allogeneic HCT with myeloablative conditioning

Myeloablative allotransplants for CLL were evaluated in trials during the 1980s and 1990s using TBI/CY conditioning regimens similar to those used in autologous HCT at the time. An early EBMT registry study of 54 patients, median age 41 years, with CLL reported a transplant-related mortality of 46% and a 3-year probability of survival of 46%. Nearly all the patients received TBI/CY conditioning and HLA-identical sibling bone marrow grafts. Ten-year clinical outcomes were reported for the entire cohort, demonstrating 41.2% OS and 36.6% leukemia-free survival [91]. This first long-term registry study suggested that CLL can be cured by conventional allogeneic HCT with long-term continuous complete remissions observed up to 16 years after transplantation. Table 59.4 summarizes a number of single-institution CLL allotransplant studies using myeloablative conditioning [91–100]. Most studies involved fewer than 30 patients. These studies, in aggregate, demonstrate

n, Number of patients; BEAM, BCNU, etoposide, Ara-C, melphalan; BM, bone marrow; BU, busulfan; CY, cyclophosphamide; GVHD, graft-versus-host disease; NR, not reported; NRM, non-relapse mortality; PFS, progression-free survival; OS, overall survival; Sib, sibling; TBI, total body irradiation; yr, year.

[a] Data for this study were not reported by type of conditioning (e.g., ablative vs. non-ablative). These results combine conditioning types.

that myeloablative allogeneic HCT for CLL using TBI/CY or CY with busulfan (BU/CY) is associated with high rates of TRM (range 24–50%). Mature OS rates at 5 years or beyond were generally around 40% (range 33–62%).

Because of the rapid adoption of reduced-intensity allogeneic HCT for CLL during the late 1990s and early 2000s, no large-scale studies of myeloablative HCT in CLL have been conducted. Sorror et al. at the Fred Hutchinson Cancer Research Center published their experience with both myeloablative and non-myeloablative allogeneic HCT for CLL and other lymphomas between 1997 and 2005 [98]; however, only 10 of 68 patients undergoing myeloablative conditioning were treated for CLL, so this study provides little additional insight into outcomes with intensive conditioning for CLL allotransplant.

Michallet et al. reported outcomes for 102 patients undergoing myeloablative and 266 non-myeloablative allogeneic HCT for CLL between 1995 and 2007 [99]. Several different conditioning regimens were used. Unfortunately, results were published with stratification by degree of donor matching (sibling, fully matched unrelated donor, and partially mismatched unrelated donor), not by type of conditioning regimen. Interestingly, however, it was reported that a multivariate analysis failed to identify conditioning intensity as an independent predictor of OS, relapse, PFS, or TRM, possibly suggesting that outcomes with myeloablative conditioning may have improved to some extent in parallel with the adoption of RIC regimens. Alternatively, a study by Brown et al. in which myeloablative and reduced-intensity regimens were analyzed by treatment era (pre- and post-2004) suggested that outcomes between myeloablative conditioning and RIC regimens were similar before 2004, but that in more recent years the outcomes achieved with RIC regimens have improved with respect to both OS and TRM [100]. Because increased conditioning intensity appears not to offer additional survival benefit, it is likely not justifiable to pursue myeloablative allogeneic HCT in patients with CLL. Similarly, a limited registry study showed that patients with CLL transformation to prolymphocytic leukemia achieved similar outcomes using ablative conditioning or RIC [101].

Reduced-intensity conditioning for CLL allogeneic HCT

Remarkable improvements in patient outcomes have been achieved through the implementation of RIC regimens for patients with CLL. This sea change in practice patterns, elicited by the recognition that engraftment and GVL effects can be robust without intensive conditioning of the recipient, has occurred fairly rapidly within the past 15 years [102].

In 1998, Khouri et al. first reported the feasibility of using fludarabine and CY-based RIC allogeneic HCT for eight patients with advanced CLL, including two patients with Richter's transformation [85]. GVL activity was demonstrated by achievement of complete responses in several patients, and also demonstration of disease clearance following a donor lymphocyte infusion (DLI) given for persistent mixed chimerism. Further early evidence of GVL in CLL following RIC conditioning included a report from Dreger et al. in which the onset of chronic GVHD following RIC allotransplant was tightly correlated with conversion from MRD detectable to undetectable status using IGH ASO-PCR [103].

Adequate engraftment and robust anti-CLL GVL activity have since been verified in many studies using a wide array of RIC conditioning regimens. Table 59.5 reviews results of a selection of RIC allogeneic HCT trials in CLL [98,100,104–112]. Most strikingly apparent is the decrease in NRM afforded by adopting regimens with less up-front toxicity. Indeed, the roughly 15–20% NRM rates in early studies represents a vast improvement over the roughly 40% NRM experienced with myeloablative regimens. Equally as important, early studies verified the presence of GVL activity in patients with even refractory CLL and those with high-risk cytogenetic changes. For the most part, equivalent outcomes have been achieved

with different RIC regimens. Schetelig et al. used fludarabine, busulfan, and antithymocyte globulin (ATG) [104], whereas the M.D. Anderson group developed FCR conditioning [106], and the Seattle group pioneered the use of low-dose TBI (2Gy) with fludarabine [107]. These different approaches yielded similar PFS of ~60% and 2-year survival rates of ~70% in early studies (Table 59.5). The 5-year follow-up from the Seattle group was published by Sorror et al. in 2008, demonstrating NRM 23%, PFS 39%, and OS 50% in 82 patients [98]. Outcomes were not affected by adverse cytogenetics and only lymphadenopathy >5cm at the time of conditioning was independently associated with treatment failure.

Similar results were reported by Dreger et al. in the German CLL Study Group in 90 patients conditioned with fludarabine and cyclophosphamide (with ATG for unrelated donors), with 4-year outcomes including NRM 23%, EFS 42%, and OS 65% [110]. Among patients with undetectable MRD at 1 year post-HCT, the risk of relapse was significantly lower [HR 0.09, 95% confidence interval (CI) 0.02–0.49, $p = 0.0052$] in comparison with those with detectable MRD. Khouri et al. at the M.D. Anderson Research Center similarly reviewed the 5-year follow-up on 86 patients undergoing RIC allogeneic HCT for CLL and reported NRM 17%, PFS 36%, and OS 51% [111].

Brown et al. at DFCI recently reported their long-term experience using fludarabine and busulfan RIC allogeneic HCT for patients with CLL [100]. Amongst 76 patients allografted between 1998 and 2009, the NRM was 16%, with PFS 43% and OS 63% at 5 years. Interestingly, this study found improved outcomes amongst the 42 patients transplanted since 2004, with just a 9.5% NRM, and an impressive 64% PFS and 83% OS at 5 years, suggesting that increasing familiarity with RIC allogeneic HCT at active transplant centers may be associated with improved outcomes over time.

Although single-center NRM decreased by more than 50% by adapting from myeloablative to RIC regimens as reported by Brown et al. [100], there remains a need to decrease NRM risk even further. To that end, the Stanford group developed a novel RIC regimen consisting of total lymphoid irradiation (TLI) and ATG, which is associated with low rates of acute and chronic GVHD, and very low rates (<5%) of NRM [113,114]. This regimen performs particularly well in patients with CLL and mantle cell lymphoma, with 4-year PFS and OS of 47 and 73%, respectively [112]. Using high-throughput sequencing-based MRD quantification, we demonstrated in a series of 40 consecutive high-risk CLL patients receiving allografts following TLI/ATG conditioning that sustained, deep remissions with no disease detectable at a 1:1,000,000 detection limit can be achieved [57].

Allogeneic HCT for CLL: patient selection

This chapter has reviewed CLL response to autologous and allogeneic HCT. Clinical prognostic criteria, including advanced Rai and Binet stage, and discrete molecular alterations, including cytogenetic abnormalities (17p and 11q deletions), unmutated IGH status, and specific immunophenotypic markers, including elevated ZAP-70 and CD38 expression, are associated with poor outcome following conventional chemotherapy treatment. Figure 59.1 presents a flow diagram incorporating clinical and molecular prognostic evaluation to guide risk-stratified treatment recommendations. It is clear that GVL alloimmunity following RIC allogeneic HCT can provide durable disease control, even for patients with poor-risk CLL, and RIC allogeneic HCT potentially cures CLL. Thus, identifying patients who warrant this approach is important so that appropriate escalation of care can commence in a timely manner.

Low risk patients have early-stage disease, with good prognosis cytogenetic findings ($13q^-$ without other changes) and mutated IGH status. At the time of diagnosis, the majority of patients have low-risk disease, and can be reassured that they are likely to have an initial asymptomatic period, and can be expectantly observed off therapy. They should be educated to recognize signs of disease progression, including lymph node enlargement, constitutional symptoms, and rapidly increasing lymphocytosis. Their clinical evaluations, including complete blood count analyses, should be obtained every 3–6 months with repeat prognostic evaluations performed when disease progresses clinically. Progressive alterations of cytogenetic and immunophenotypic characteristics suggest that CLL undergoes clonal evolution in association with more aggressive disease behavior, and supports repeating CLL molecular assessment when disease progression or treatment failure necessitates new therapy.

Intermediate-risk patients have normal cytogenetics or trisomy 12, in addition to mutated IGH gene status. Intermediate-risk disease is also defined by clinical progression scored by the Rai and Binet intermediate stages and their symptomatic problems warrant standard combination chemo-immunotherapy treatments, including purine analog therapy combined with anti-CD20 monoclonal antibodies, with front-line preference for the FCR regimen, or possibly BR in selected patients unable to tolerate FCR. The goal of this combination therapy is symptomatic relief. Those patients with persistent CLL or who have progression within 2 years of fludarabine-based therapy should be considered for more aggressive salvage therapies, clinical trial protocols, or RIC allogeneic HCT, since fludarabine-refractory patients have a 10-month median survival and only 22% respond to first-line salvage chemotherapy [115]. Once a CLL patient achieves CR, they should be closely followed with routine clinical and CBC assessment for evidence of disease progression every 3 months.

High-risk patients are not defined by their clinical stage, but are strongly predicted by cytogenetic abnormalities $11q^-$ and $17p^-$, unmutated IGH gene status, and IGH V3–21 usage. Such CLL patients may demonstrate additional poor prognostic factors defined by their clinical course: resistance or incomplete response to fludarabine [63,115] and short time from diagnosis to first therapy (<12 months) [116]. Thus, in Figure 59.1, high-risk patients follow a treatment course that begins with standard combination therapy to cytoreduce their disease, and once they achieve adequate disease control, they should immediately be considered for RIC allogeneic HCT. RIC allogeneic HCT does not include high-dose chemotherapy and high-risk patients who do not achieve adequate disease control (PR or better with lymphadenopathy <5cm in largest dimension) should proceed to additional salvage therapies, including alemtuzumab containing [e.g., cyclophosphamide, fludarabine, alemtuzumab, and rituximab (CFAR)] [117] or platinum doublet-containing regimens [e.g., oxaliplatin, fludarabine, cytarabine, and rituximab (OFAR)] [118], novel agents, or clinical trials to gain better disease control before proceeding to RIC allogeneic HCT.

Treatment of post-transplant relapse

Although overall outcomes have improved significantly with the use of RIC allogeneic HCT for high-risk CLL patients, 35–50% of patients will still experience disease relapse following transplant. Post-transplant relapse may be successfully managed using immunomodulation strategies, including immune suppression withdrawal (ISW), donor lymphocyte infusion (DLI), chemotherapy and/or antibody therapy followed by DLI, or a clinical trial. Rondón et al.

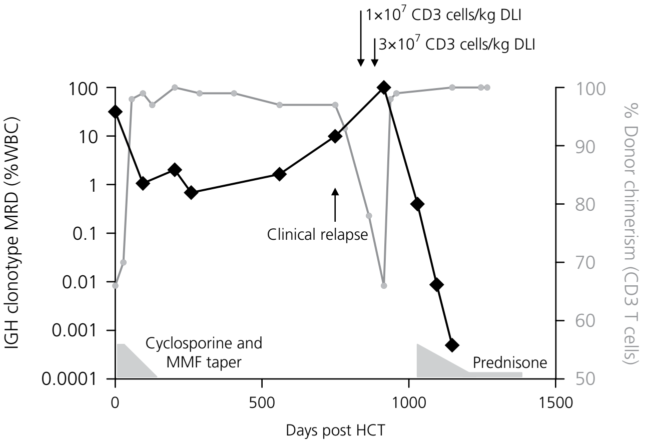

Figure 59.2 GVL effect. This graph shows the course of a 60-year-old man diagnosed with Rai stage III CLL with 17p deletion and unmutated IGH, who was treated with several chemotherapy regimens (FCR, R-CHOP, CFAR, OFAR), achieving only short-lived PRs. He proceeded to RIC allogeneic HCT using TLI/ATG conditioning and a matched unrelated donor. At the time of conditioning, he had persistent CLL, including bulky lymphadenopathy and 20% bone marrow infiltration. CR was achieved for roughly 2 years. Subsequent relapse was effectively controlled with two DLIs.

reported a case in 1996 in which post-allograft CLL relapse went into complete remission following a DLI 87 days after transplant [119]. Español et al. demonstrated in 2003 that even Richter's transformation occurring after allogeneic HCT can be effectively treated with ISW and DLI [120]. An example of this GVL effect is shown in Figure 59.2. Since these early reports, many of the studies discussed above have reported the use of immunomodulation and DLI to achieve durable complete remissions in CLL patients relapsing after allogeneic HCT. The roughly 20–25% gap between 4–5-year PFS and OS observed in several studies is due, in part, to the ability to salvage a substantial proportion of relapsed CLL patients using DLI. In fact, in a meta-analysis of DLI activity in different hematologic malignancies, CLL had the highest likelihood of response (55%) in comparison with non-Hodgkin lymphoma (52%), Hodgkin lymphoma (37%), acute lymphoblastic leukemia (27%), and multiple myeloma (26%) [121]. Khouri et al. treated half of the 86 patients in their study with post-HCT ISW and DLI, with a median number of additional cell infusions of two (range 1–8) starting roughly 6 months (range 63–909 days) after HCT [111]. Of these patients, 47% subsequently achieved a CR and the median survival for this group had not yet been met with 47 months of follow-up (range 5.4–110.2 months). In contrast, the median survival for those not achieving CR with DLI was 35 months. The most important determinants associated with favorable response to immunomodulation were achievement of complete donor chimerism at day 90 post-HCT and being HLA-A1 positive/HLA-A2 negative/HLA-B44 negative, suggesting that more studies are needed to understand better the parameters affecting GVL alloimmunity to make more effective use of this treatment strategy.

Novel agents in CLL

Post-transplant relapse is a scenario in which participation in a clinical trial or use of novel therapies that have become available is warranted. Several recent treatment innovations are likely to become more widely available in the near future and will be relevant considerations for salvage therapy following CLL relapse post-HCT. Ofatumumab, a humanized anti-human CD20 antibody, has activity in rituximab- and alemtuzumab-refractory CLL and may be a reasonable consideration [122], although there are not yet any published data in the post-allogeneic HCT setting. Lenalidomide, when used in conjunction with rituximab, has shown promise for the management of relapsed/refractory CLL, with a 66% overall response rate [123], and may be capable of inducing complete molecular remission [124]; however, its use in the post-allograft setting may be associated with induction or worsening of GVHD [125,126]. Small molecular inhibitors of B-cell receptor signaling also promise to be of potential use for patients with post-HCT CLL relapse. Ibrutinib, an irreversible inhibitor of Bruton's tyrosine kinase available as an oral medication, is well tolerated and highly active in relapsed/refractory CLL [127,128], and if preliminary data are confirmed, this agent may play a critical role in the management of CLL post-HCT relapse. Indeed, these and other novel agents will likely become increasingly prominent in the treatment of CLL prior to consideration for allogeneic HCT, especially those, such as ibrutinib, that appear to be active in 17p-deleted CLL [34]. Only long-term follow-up and appropriate comparative trials will be able to determine whether novel agents will obviate the utility of allogeneic HCT in high-risk CLL.

Cell therapy

As discussed above, CLL is susceptible to GVL alloimmunity, but conventional allogeneic HCT also conveys the risk of GVHD. The ability to redirect autologous or allogeneic T-cell activation in response to specific antigens has recently been demonstrated by the introduction of chimeric antigen receptors (CARs). This is discussed in Chapter 69.

Conclusion

CLL is a heterogeneous disease at the molecular and clinical levels. Strategies for identifying high-risk patients now permit early consideration of transplant therapies for young and appropriate elderly patients. Although autologous HCT is feasible and associated with good outcomes, this approach does not appear to cure patients of their CLL, and the procedure is associated with a high rate of secondary malignancies. Myeloablative allogeneic HCT may cure some patients, but several studies have demonstrated that this benefit comes at an unacceptable cost in the form of very high non-relapse mortality. RIC regimens appear to offer benefits of engraftment with less toxicity and opportunities to achieve disease control via GVL activity with or without post-HCT immunomodulation. A wide array of novel treatments for CLL have recently shown early-phase efficacy, and we expect the next many years to be a period of dynamic change in common treatment algorithms for patients with CLL. Increasingly standardized molecular and/or MPFC-based MRD quantification will enable depth of response to be more precisely quantified and early progression to be detected, and it is likely that these methods will eventually facilitate the identification of patients likely to require GVL alloimmunity for adequate disease control. In the meantime, existing patient selection criteria should be used for identifying those who may benefit from RIC allogeneic HCT so that preparations for this therapy may be made prior to the development of highly treatment-refractory disease.

Introduction

The amyloidoses are diseases in which abnormal proteins self-assemble and form extracellular deposits of insoluble non-branching linear fibrils that are 7–10nm in width, vary in length, and resist proteolysis [1]. Medical investigators at autopsy recognized such deposits over three centuries ago and thought that the material was a fatty substance, hence the term “lardaceous disease” [2]. In 1854, the pathologist Virchow described the deposits in postmortem liver tissue with the botanical term “amyloid,” meaning starch, because of the starch-like affinity that the deposits had for iodine. When viewed in visible light after hematoxylin–eosin staining, the deposits appear amorphous, hyalinized, and eosinophilic, but when viewed in polarized light after Congo Red staining, the deposits exhibit a characteristic color change from hyaline pink to flaky yellow–green, a dichromic or birefringent feature first reported in 1927 (Figure 60.1) [3]. A century after Virchow, the fibrillar nature and characteristic β-pleated sheet configuration of amyloid were identified by electron microscopy (Figure 60.1) [4,5]. In the 1970s, researchers established that all amyloid variants have fibril-precursor proteins which self-assemble into filaments and then fibrils [6,7]. Directly determining the type of amyloid in a patient’s tissue biopsy, however, remained a challenge until decades later when laser microdissection (LMD), trypsin digestion, and mass spectrometry (MS) of protein fragments with bioinformatic analysis permitted the definitive determination of type, provided that a patient’s diagnostic biopsy showed amyloidosis by Congo Red staining and contained sufficient deposits amenable to microdissection [8].

The type of amyloid is a function of the fibril-precursor protein that causes the deposits. Currently, the classification system designates the amyloid-forming protein by the first letter A for amyloid and subsequent letter(s) for the fibril-precursor protein; for example, L for light chain (AL) and TTR for transthyretin (ATTRm or ATTRwt; m = mutant or hereditary and wt = wild-type) [9]. The type of amyloidosis also designates the disease. In patients with amyloidosis associated with chronic inflammatory conditions (so-called “secondary” or AA), the fibril-precursor protein is the acute-phase apolipoprotein serum amyloid A (SAA). The gene encoding SAA has three variants, only one of which is associated with AA. In patients with hereditary amyloidosis, the fibril-precursor protein is often a mutant form of the homotetrameric protein TTR, a transporter of thyroxine and retinol. Point mutations cause amino acid substitutions that facilitate dissociation of the tetramer into monomers, conformational instability of the non-native monomers, and monomer misfolding with subsequent self-assembly. Other mutant proteins can also cause hereditary amyloidosis, including fibrinogen Aα, apolipoproteins I and II, and lysozyme. More than 100 mutant forms of TTR have been identified as causes of ATTRm hereditary amyloidosis [10]. In patients with age-related amyloidosis (also called senile systemic or senile cardiac amyloidosis), who are almost exclusively elderly men, the fibril-precursor protein is wild-type TTR (ATTRwt) [11]. Dissociation likely occurs as a consequence of abnormal glycosylation. The etiology of this age-related form of amyloidosis is poorly understood but, in contrast to the rapidly progressive clinical course of cardiac amyloidosis due to AL, ATTRwt with cardiac involvement typically has a more indolent course with atrial arrhythmias and heart failure that worsen gradually over years. Therapies currently available for both mutant and wild-type forms of TTR-related amyloid disease stabilize the tetramer and impair the accumulation of misfolded monomers [12].

In patients with light chain (AL-) amyloidosis, the fibril precursors are usually free light chains (FLCs) possessing an abnormal tertiary structure. These FLCs both aggregate into oligomers that may be toxic to cellular metabolism and assemble as filaments of β-pleated sheets that coil together to form relatively insoluble fibrils. Both AL-amyloidosis and multiple myeloma are clonal plasma cell disorders, but what distinguishes symptomatic AL-amyloidosis from symptomatic multiple myeloma is the pattern of organ damage. AL-amyloidosis typically involves the heart, causing a restrictive cardiomyopathy, the kidneys in the form of albuminuria due to glomerular amyloid deposits, the liver and gastrointestinal tract, and the peripheral nervous system. Myeloma typically involves bones in the form of lytic disease and hypercalcemia, kidneys in the form of Bence Jones proteinuria and cast nephropathy resulting in acute kidney injury, and bone marrow hematopoiesis, causing anemia and other cytopenias. It is not typical for the clinical course of a patient with AL-amyloidosis to be significantly impacted by associated myeloma organ damage. Patients with AL-amyloidosis who do not have myeloma at presentation have a small risk of subsequent evolution to frank multiple myeloma and 10–15% of

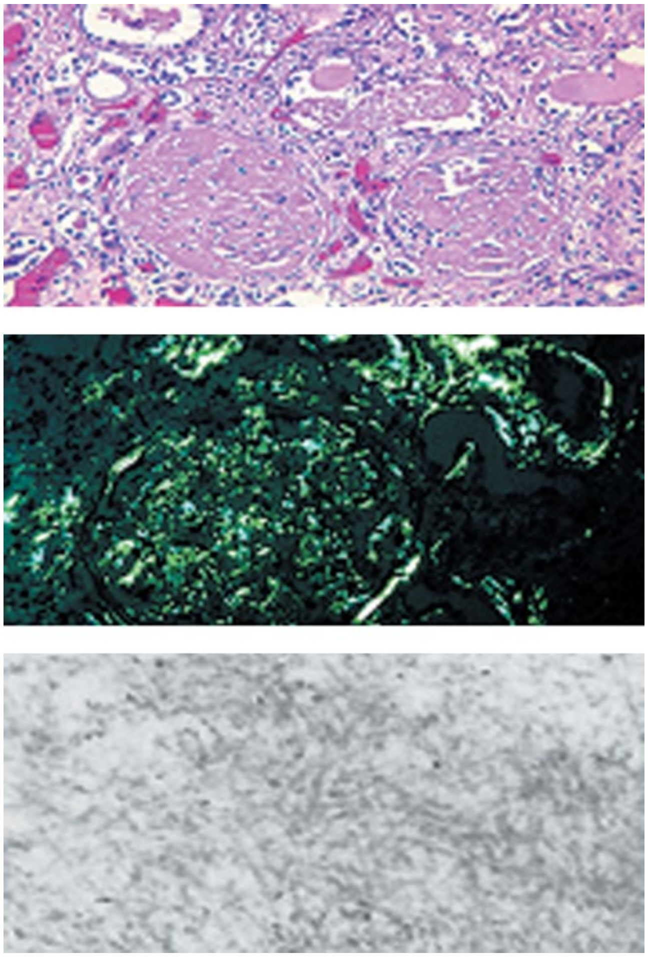

Figure 60.1 Renal biopsy showing amyloidosis. These images show three views of a renal biopsy: with periodic acid–Schiff (PAS) staining showing amorphous material in glomeruli (top), Congo Red staining showing apple-green birefringence in polarized light (middle), and electron microscopy showing non-branched linear fibrils about 10nm in length. (For a color version of this figure, please see the color plate section.)

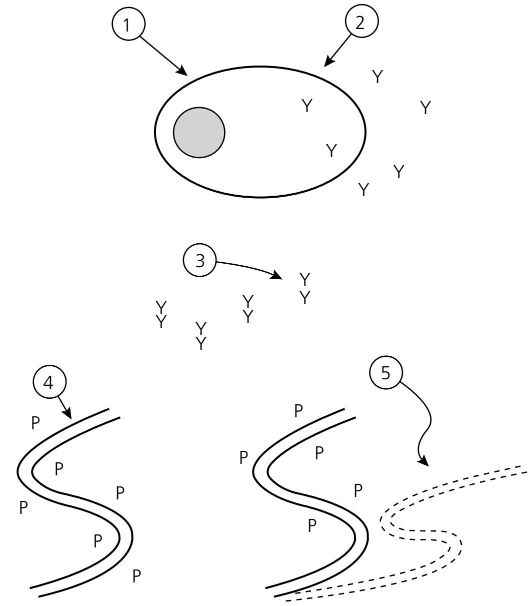

Figure 60.2 Theoretical remedies for AL-amyloidosis. There are a number of points at which intervention could, in theory, control AL-amyloidosis: (1) reducing the number of plasma cells with cytoreductive therapy; (2) reducing the secretion of clonal free light chains with drugs; (3) impairing the self-assembly and aggregation of light chains; (4) inhibiting fibril formation in tissues; and (5) dissolving or enhancing the proteolysis of amyloid fibrils. Remedies that reduce the number of plasma cells include standard- and high-dose chemotherapy. Although it is currently not available, 4-iodo-4-deoxydoxorubicin (IDOX) may enhance the proteolysis of fibrils. The other possible remedies remain theoretical.

myeloma patients may develop amyloidosis during the course of their disease. Furthermore, at diagnosis high-risk AL-amyloidosis is defined based on the extent of cardiac involvement, whereas high-risk myeloma is defined based on the genetics of the clonal disease. The distribution of heavy and light chain isotypes, and also the distribution of clonal cytogenetics and fluorescent in situ hybridization (FISH) abnormalities, differ in AL-amyloidosis and myeloma; however, the agents and approaches used to treat them are similar. In AL-amyloidosis, 75% of the pathologic clones are λ isotype whereas in myeloma only 40% are, a difference that reflects an intrinsic amyloid-forming propensity of λ light chains.

AL-amyloidosis is a disorder both of protein conformation and of clonal plasma cells [13]. In theory, the treatment of AL-amyloidosis could be directed at various aspects of its pathogenesis (Figure 60.2). Most frequently, as in myeloma, therapies have aimed to reduce or eliminate clonal plasma cells, the source of the aberrant FLCs. By the mid-1990s, no significant progress had been made with standard chemotherapy in reversing the inexorable progression of systemic AL-amyloidosis, not surprisingly in view of the visceral dysfunction it causes. At that time, because the efficacy of autologous hematopoietic cell transplantation (HCT) had been demonstrated in myeloma, HCT was tested in systemic AL-amyloidosis [14,15]. When HCT was successful, the organ damage could be reversed, the production of deposits halted, and prior amyloid deposits slowly resorbed. Organ function, performance status, and quality of life improved [16,17]. The achievement of a hematologic complete response (CR), as defined for that era, led to clinical and functional improvement and prolonged survival; however, in the early clinical trials, transplant-related mortality was high because the organ reserve of patients was compromised by cardiac, gastrointestinal, renal, and neuropathic amyloid involvement. This made patients with AL-amyloidosis different from other stem-cell transplant candidates. The evolution of HCT for patients with AL-amyloidosis has been characterized by refinement of patient selection, improvement of peri-transplant clinical management, and recently by application of post-HCT adjuvant therapy with novel agents and the development and application of validated consensus response criteria [18–21]. In this chapter, we describe the epidemiology, pathogenesis, and distinctive clinical aspects of this disease, offer an approach to the evaluation of patients with AL-amyloidosis, and summarize recent clinical research in HCT for AL-amyloidosis.

Epidemiology

The epidemiology of AL-amyloidosis is difficult to define because the disease often goes undiagnosed. Data from tertiary referral centers are not necessarily representative. AL-amyloidosis is a rare disorder with an age-adjusted incidence estimated to be 5.1–12.8

per million person-years, resulting in approximately 1275–3200 new cases annually in the United States and 255–640 cases in the United Kingdom, an incidence similar to that of chronic myelogenous leukemia or Hodgkin disease. AL-amyloidosis appears to be more common in men, but no links with race, occupation, or environmental exposures have been reported. Summary data on over 800 patients from centers in six countries are shown in Table 60.1 [21].

Pathogenesis

The final pathway in the pathologic process of AL-amyloidosis is the formation and deposition of fibrils [22]. When the AL amyloid subunit proteins are solubilized and deciphered by amino acid sequencing, the dominant constituents of deposits are the light chain variable and constant regions and less frequently the whole immunoglobulin [8,23,24]. Although the reason why some FLCs form amyloid remains unknown, comparisons of the primary structures of normal and amyloid-forming FLCs have provided some insight based on the aberrant properties of the pathologic FLCs [25]. Analyses of primary structure have emphasized the critical contribution of uncommon amino acid substitutions to the stability and interactive properties of misfolded or partially folded light chains [26]. Such partially folded intermediate forms may be prone to self-assemble. The identification of potentially destabilizing uncommon amino acid substitutions at unique positions in amyloid-forming FLCs has supported this hypothesis. Purified urinary light chains from patients with AL-amyloidosis reproduce fibrillar disease when injected into mice, whereas those from myeloma patients without AL-amyloidosis do not [27].

If the pathogenesis of AL-amyloidosis were a function of fibrillar amyloid burden, however, patients with minimal tissue deposits would be relatively asymptomatic. However, this is not always the case. A patient's clinical status is not determined simply by amyloid burden. Patients with peripheral nervous system or cardiac involvement can have minimal tissue amyloid but experience symptomatic organ dysfunction. Conversely, a significant fraction of patients who respond to treatment with elimination of the monoclonal FLCs do not show a reduction in amyloid burden despite clinical improvement and abatement of symptoms, when burden is evaluated with serial iodine-123-labeled serum amyloid P protein (SAP) total body scintiscans [28]. Such observations have led to the view that amyloid fibrils per se may not be the sole pathologic basis of the disease [29,30]. Moreover, experiments in vitro with several fibril-precursor proteins have shown that intermediate oligomers or oligomeric aggregates may be toxic to cells [31,32]. This has led to the view that fibrils may represent a more benign form of the precursor protein and may provide relative protection from cellular toxicity until the burden of fibrils overwhelms the involved organ [1]. The relationship between oligomers and fibrils in the various types of amyloidosis remains undefined, and the mechanistic role of intermediates in the disease is unclear. Therefore, we currently live with the paradox that while pathologic FLCs cause symptoms in patients with AL-amyloidosis, we cannot make the diagnosis of AL-amyloidosis without evidence of tissue deposits.

Table 60.1 Patient characteristics (*N* = 816) (data pooled from six countries) [21]

Characteristic	*n* (%) or median (25th–75th centile)

Bortezomib based	26 (3.2)
Dexamethasone alone	24 (2.9)
Melphalan + prednisone	20 (2.4)
Other	91 (11.1)

How amyloid fibrils cause organ dysfunction is not known, and how fibrils are metabolized and organs improve is no less a mystery. The liver, for example, can tolerate a large burden of amyloid without failing and, once treatment eliminates the supply of FLCs, the liver can respond with restoration of normal synthetic function and dramatic regression to normal size. These changes can happen over months. This is attributed to the regenerative capacity of the liver but begs the question as to how the fibrils are removed. Removal, when it occurs, may be related to the presence of other components of the fibrillar deposits. The interactions between amyloid-forming FLCs and the passenger constituents of amyloid deposits, such as glycosaminoglycans and apolipoproteins, may be related to the amino acid variations noted earlier, and may influence the course of disease by stabilizing filament and fibril formation and by modifying the sensitivity of fibrils to proteolysis [33]. These passenger constituents are reliably identified in the amyloid deposits evaluated by LMD/MS and provide an internal validation or control with respect to the accuracy of the technique. A major component of amyloid deposits is serum amyloid P-component (SAP), a member of the pentraxin protein family that is highly resistant to proteolysis and likely acts as a pathologic chaperone for fibrils [34]. SAP employs a calcium-dependent binding mechanism in its interactions with amyloid fibrils and may contribute to the occurrence of deficiencies in calcium-binding vitamin K-dependent coagulation factors, most notably Factor X, a clinical feature associated with hepatosplenic amyloidosis.

Monoclonal FLCs and minimal bone marrow plasmacytosis are detected in the majority of patients with AL-amyloidosis, often in association with suppression of non-involved immunoglobulin production [21,35]. About 60% of patients have marrow biopsies showing 10% or fewer clonal plasma cells [36]; 11% of patients with amyloid have over 20% plasma cells with no evidence of myeloma-defining organ damage. When a clonal immunoglobulin heavy chain is detectable in the serum, it is IgM in 7% of cases. The presence of IgM amyloidosis is not well recognized; these patients usually do not have Waldenström macroglobulinemia [37]. The clones that cause AL-amyloidosis are distinct from myeloma clones with respect to their repertoire of immunoglobulin light chain variable germline (Ig *VL*) genes, but similar in that their immunoglobulin genes are highly mutated (i.e., they are antigen-driven or post-germinal center clones) [38–40]. The repertoire of Ig *VL* genes in AL-amyloidosis is skewed, unlike that in myeloma, which is similar to the normal expressed repertoire. Half of AL clones employ one of three immunoglobulin λ light chain variable region germline genes: *IGLV2-14* [*2a2*; Z73664], *3r* (Z73647) or *IGLV6-57* [*6a*; Z73673]. AL clones using genes derived from the *3r* germline donor have a significantly higher divergence from the germline sequence than those using the *IGLV6-57* donor, a difference possibly related to both antigen selection and the inherent amyloid-forming propensity of IGLV6-57 light chains [38,41].

A puzzling feature of AL-amyloidosis is the variety of organs that can be affected. Although the basis for this tropism is unknown, evaluations of the immunoglobulin light chain genetics underlying AL-amyloidosis suggest that some light chain variable region germline donor genes are more likely to give one pattern of organ involvement than another [38,42]. Using the reverse transcriptase polymerase chain reaction to clone amyloid-forming FLC genes, and available databases for germline gene identification, several investigators have sought to test the hypothesis that the light chain variable region genes used by AL-amyloidosis plasma cell clones influenced organ tropism. In one series, light chain variable region germline genes were identified from 60 patients with AL-amyloidosis. Dominant renal involvement was linked to clones whose FLCs were derived from the *IGLV6-57* germline gene, while dominant cardiac and multisystem disease was linked to those with FLCs derived from the *IGLV2-14* and *3r* genes [38]. Despite these suggestive data, we do not know how the assembly of abnormal FLCs causes progressive organ dysfunction and clinical disease, often at a rapid tempo, nor do we know how partially folded light chain intermediates may be more toxic to cellular metabolism than fibrillar deposits [43].

Clonal AL plasma cells harbor recurring cytogenetic abnormalities, including t(11;14), del 13q and gain 1q, while t(4;14) and del 17p are not typically seen [44–46]. Interestingly, the t(11:14) was associated with worse overall survival (OS) in a series of AL-amyloidosis patients, in contrast to its association in myeloma with a relatively favorable prognosis [46]. Moreover, overexpression of *cyclin D1* in purified AL plasma cells occurs in half of patients and is associated with a high frequency of light chain M-proteins and kappa light chain-producing clones [47]. Trisomies of chromosomes 7, 9, 11, 15, and 18 have also been reported in 33–52% of patients, and trisomy X in 13% of women and 54% of men. Immunoglobulin heavy chain translocations have been reported in 55% of patients, and abnormalities of chromosome 13 are frequent [48].

Diagnosing AL-amyloidosis

The most common symptoms of amyloidosis are fatigue, weight loss, dyspnea, edema, and paresthesias. The fatigue, generally caused by cardiac involvement, may be misdiagnosed as functional or stress related since the usual features of congestive heart failure are absent. Light-headedness is common. It can occur in patients with nephrotic syndrome with hypoalbuminemia and contraction of plasma volume, and in patients early in the course of cardiac amyloidosis due to poor diastolic filling, a reduced stroke volume, and autonomic dysfunction. Often such patients have orthostatic hypotension but a normal echocardiographic ejection fraction. Amyloidosis patients with autonomic neuropathy also often have orthostatic hypotension, frequently associated with syncope. Amyloidosis should be considered when patients with a monoclonal gammopathy complain of fatigue, weight loss, and vague constitutional symptoms.

The physical findings of amyloidosis are specific but not sensitive. Purpura are seen in only one patient in six, most commonly on the eyelids, upper face, and webbing of the neck. A palpable liver is present in one-quarter of patients and may be due to infiltration of the liver or congestion related to elevated right-sided cardiac pressures. Enlargement of the tongue is the most specific finding, but is seen in only one patient in 10. It is easily recognized because it results in dental indentations on the tongue laterally and inferiorly, and enlargement of the submandibular salivary glands, often misdiagnosed as enlarged lymph nodes. An occasional patient will present because of vascular claudication due to small vessel occlusion with amyloid deposits.

Because the symptoms and physical findings are not diagnostic of amyloidosis, it is important to recognize the clinical syndromes associated with AL-amyloidosis. The seven most common presentations are infiltrative cardiomyopathy, nephrotic-range proteinuria, hepatomegaly, demyelinating peripheral neuropathy, carpal tunnel syndrome, macroglossia, and intestinal pseudo-obstruction. When one of these clinical syndromes is seen, the next step is to perform serum FLC and immunofixation studies of serum and urine. A screening serum protein electrophoresis is inadequate because of the high prevalence of light chain-only disease. Since many patients have significant degrees of albuminuria, an M-protein peak may be obscured in the urine protein electrophoresis, necessitating immunofixation. Serum FLC and/or immunofixation studies will be abnormal in over 95% of patients, and the serum FLC assay has demonstrated abnormal circulating FLCs even when the serum and urine immunofixation studies are negative [49].

Since AL-amyloidosis is usually a plasma cell disease, the finding of a monoclonal light chain in a patient with a consistent clinical syndrome is an indication to obtain a tissue biopsy for diagnosis. Rarely, AL-amyloidosis can be associated with mature B-cell non-Hodgkin lymphomas that produce clonal FLCs [50].

FLCs unassociated with heavy chains are produced in slight excess by normal plasma cells and in significant excess at times by clonal plasma cells. FLCs circulate in normal individuals and can be measured with the FLC assay. This assay is quantitative, unlike immunofixation, and is a more sensitive measure of the presence of clonal disease than immunofixation in many cases. FLC levels and ratios are abnormal in more than 95% of patients with AL-amyloidosis, and the elevated FLCs usually are the precursor protein [51,52]. When the diagnostic evaluation includes serum FLCs, serum and urine immunofixation, and clonal analysis of marrow biopsy for plasma cells, all patients with AL-amyloidosis should be recognized. If evidence for clonal plasma cell disease cannot be detected, the type of amyloidosis remains in question, and one should consider forms of non-AL-amyloidosis such as localized, age-related, or hereditary [53].

The diagnosis of amyloidosis is made by biopsy, as is standard for patients with malignancy. Patients with visceral involvement of the kidneys, heart, liver, or soft tissues may have the diagnosis confirmed by involved organ biopsy. The nature of amyloid, however, is that there is widespread deposition in blood vessels at diagnosis, and less invasive biopsies will readily establish the diagnosis. The abdominal fat is a validated surrogate site and will contain Congophilic amyloid deposits in 80% of patients, although false positives due to overstaining can sometimes be seen [54]. A bone marrow biopsy will demonstrate Congophilic deposits in 56% of patients, although marrow is not considered a valid surrogate site [55]. Other sites that can be safely biopsied include the skin, minor salivary glands, and rectum. Visualizing amyloid in visceral biopsies with both Congo Red staining and electron microscopy enhances diagnostic confidence.

The evaluation at diagnosis includes testing for organ involvement and, if indicated, for type of amyloid. Concerns about whether a patient has AL-amyloidosis or another type are warranted because myelotoxic chemotherapy has no place in the treatment of non-AL-amyloidosis, and also because failure to diagnose a hereditary disease has consequences [56,57]. Family history is not a useful guide for hereditary disease and, with the exception of renal biopsies, tissue staining for amyloid typing is unreliable. Investigators at two centers have reported patient series (n = 178, n = 350) in which 2–10% of patients presumed to have AL-amyloidosis had both a monoclonal gammopathy and a hereditary mutant protein, either transthyretin or fibrinogen Aα. Of note, a hereditary mutant transthyretin (the valine-122-isoleucine variant) occurs in 4% of African-Americans, a racial group that also has a higher incidence of monoclonal gammopathy [58]. Therefore, African-Americans with amyloid and a monoclonal gammopathy need to have their amyloid typed. We also recommend amyloid typing in patients presenting with a monoclonal gammopathy and either peripheral neuropathy or a concurrent immune disorder such as Sjogren syndrome or rheumatoid arthritis. Patients with two possible amyloid-forming proteins should be referred to centers specializing in amyloidosis for typing and treatment. Amyloid typing is also indicated in patients with amyloid by tissue biopsy with no apparent amyloid-forming protein.

The gold standard for typing amyloid is based on modern proteomic techniques. In the United States, LMD/MS, a Clinical Laboratory Approved Amendments (CLIA) approved test, employs customized bioinformatic assessment of the protein fragments from digested and fractionated Congophilic tissue deposits to identify type reliably in over 98% of cases [8]. LMD/MS is specifically indicated in cases where two potential amyloid precursor proteins are present or where none is apparent. Importantly, LMD/MS identifies the chaperone and fellow-traveler elements in amyloid deposits and also the amyloid-forming protein, providing an internal validation unavailable for any other tissue or protein-based technique. DNA sequencing of genes related to hereditary variants is also a useful tool, particularly for confirming proteomic findings and screening family members. It is important to note that LMD/MS and other proteomic techniques provide probability-based read-outs of protein constituents of Congophilic deposits, hence the use of multiple samples from one specimen or of tissue controls from normals [59]. Occasionally, serum proteins, particularly very low levels of kappa free light chains, can be identified in the read-outs, likely representing serum protein contamination; in our experience, however, these low-level contaminants can be discounted with respect to typing and treatment, although we remain curious as to their significance.

The practitioner who rarely sees patients with amyloidosis must also be sensitive to the occurrence of localized AL- or systemic age-related amyloidosis (ATTRwt). The skin, larynx, tracheobronchial tree, lungs, duodenum, and bladder are the most common sites of localized AL-amyloidosis. Localized rarely progresses to systemic disease. Age-related systemic amyloidosis usually presents with less aggressive cardiac involvement in men over 70 years of age, although the lungs may be symptomatically involved and progression can be rapid in rare cases [60]. Patients who may have localized or age-related systemic amyloidosis should also be referred to centers specializing in amyloidosis for diagnostic confirmation and recommendations regarding therapy and supportive care.

Clinical presentations

Heart

Heart involvement carries the most serious prognosis because its extent directly impacts survival [61]. The pathophysiology is infiltration of the myocardial wall leading to restriction of ventricular filling and extensive vascular involvement causing ischemia and myocardial cell drop-out. Vascular deposits in small coronary arterioles can be demonstrated on endomyocardial biopsy and can produce angina.

Patients may present with disabling fatigue and unexplained weight loss as the only symptoms. The electrocardiogram can show low voltage with no prior history of an ischemic event. The echocardiogram shows thickening of the wall, commonly misinterpreted as concentric left ventricular hypertrophy rather than infiltration. The ejection fraction is usually preserved. Thickening of the mitral and tricuspid valves due to amyloid infiltration is often an important clinical clue. Exercise-induced syncope has been associated with a median survival of 2 months [62]. Any patient with intractable fatigue or an echocardiogram showing a thickened wall needs to have studies for the presence of a monoclonal protein in the serum or urine.

A role for cardiac biomarkers has been established in AL-amyloidosis [63,64]. A staging system using both N-terminal fragment of pro-brain natriuretic peptide (NT-proBNP) and troponin has been developed [65]. Cardiac involvement is prevalent; therefore, these biomarkers are useful in screening. Patients with pronounced elevations of both NT-proBNP and troponin have a poor prognosis [66]. These biomarkers are useful in the management of patients and can decrease in cardiac patients when the clonal FLCs are reduced with therapy. Because cardiac involvement is the major determinant of survival and changes in cardiac function following therapy can be reliably assessed using NT-proBNP levels, changes in FLCs and NT-proBNP predict survival as early as 3 months after treatment initiation [21].

The mainstay of management of cardiac amyloidosis is diuretics. Many patients will have associated orthostatic hypotension and intravascular volume contraction secondary to nephrotic syndrome, making diuretic therapy difficult. The use of diuretics may precipitate syncope and can reduce renal blood flow, with a resultant rise in the serum creatinine level. The high frequency of hypotension in AL-amyloidosis can make the use of angiotensin-converting enzyme inhibitors and receptor blockers difficult. Also, stasis frequently leads to thrombi in the right and left ventricles, potential sources of embolism that may complicate the course of HCT. These thrombi can occur even in patients in normal sinus rhythm.

Kidneys

Over 60% of patients with AL-amyloidosis will have renal involvement [21], and the most common presentation of renal amyloidosis is albuminuria. About 30% of all patients will have proteinuria above 3g/day [36]. Amyloidosis is demonstrated in 3% of renal biopsies [67]. The major clinical consequences of renal amyloid are severe serum hypoalbuminemia and eventual renal failure. The loss of albumin results in reduced intravascular oncotic pressure and edema of the lower extremities and presacral area and, in severe cases, can lead to anasarca, ascites, and pleural effusions. The edema generally requires diuretics for control, but diuresis may aggravate intravascular volume contraction and exacerbate hypotension. The principal long-term complication of continuous urinary protein loss in renal amyloid is tubular damage that results in end-stage renal failure. One of the goals of HCT is to eliminate the high urinary protein losses and therefore delay or prevent the need for dialysis. The presenting 24-hour urine protein and serum creatinine predict which patients will ultimately develop end-stage renal disease. In historical cohorts, the median time from diagnosis of AL-amyloidosis to dialysis was 15 months and the median survival from the start of dialysis was 8 months. This poor outlook justified the use of HCT in patients with single-organ renal involvement. The extent of amyloid deposits seen on a renal biopsy does not correlate with the severity of proteinuria and hypoalbuminemia. Limited amyloid deposits can be associated with advanced nephrotic syndrome. The kidneys are normal in size in amyloid. If amyloid does not involve the kidneys at presentation, it rarely occurs during follow-up.

Patients with higher levels of proteinuria have greater morbidity associated with pre-transplant conditioning, including increased fluid retention and transient acute renal failure [68]. Post-HCT in renal responders, median time to response was 10 months (range 1–40 months) [69]. Renal response was associated with a longer survival than hematologic response alone. Severe proteinuria and high troponin negatively affected renal response after autologous stem-cell transplantation. Achievement of renal response was associated with improved survival [69]. Renal transplantation has been performed in patients with AL-amyloidosis and HCT for AL-amyloidosis has been performed successfully both before and after renal transplantation [70,71].

Liver and gastrointestinal tract

Hepatomegaly is found by physical examination in one-quarter of patients with AL-amyloidosis, usually associated with an unexplained elevation of the serum alkaline phosphatase level and early satiety. The majority of patients are symptomatic [72]. Hepatomegaly may be due to amyloid-induced heart failure or direct infiltration of the hepatic parenchyma. Half of the patients with hepatic amyloid have more than 1g of daily proteinuria [72]. The clues that allow the recognition of hepatic amyloid are hepatomegaly out of proportion to the degree of abnormal liver function tests, elevated alkaline phosphatase, a monoclonal protein in the serum or urine, Howell–Jolly bodies in the peripheral blood film (due to splenic infiltration), and proteinuria. Most patients will have only alkaline phosphatase elevation with normal transaminases. The median elevation of the serum alkaline phosphatase value in AL-amyloidosis patients with hepatic involvement is 2.3 times the upper limit of normal. Elevation of the serum bilirubin is generally a preterminal finding. The presence of hyposplenism on the peripheral blood film is specific for splenic amyloid. Rarely, a patient can have splenic or hepatic rupture, or portal hypertension with varices and bleeding. Ascites is usually due to associated nephrotic syndrome, hypoalbuminemia and congestive heart failure, and is not associated with portal hypertension.

Fewer than 5% of patients with AL-amyloidosis will present with symptoms referable to the gastrointestinal tract [73]. The presence of anorexia and weight loss does not correlate with the presence of gastrointestinal amyloid deposits. Malabsorption with steatorrhea is seen in less than 5% of patients. When symptoms are present, they most often include weight loss and bleeding. Patients with advanced gastrointestinal tract involvement can require long-term total parenteral nutrition for management. These patients have intractable nausea and vomiting, and do not respond to enteral feeding or pharmacologic interventions. The most common presenting symptoms are diarrhea, anorexia, dizziness, and abdominal pain. They will frequently have vitamin K deficiency due to malabsorption and low Factor X levels. Computed tomography scanning demonstrates thickening of the bowel wall. There is usually a significant delay from the onset of symptoms to the recognition of amyloid. In our experience, the median time from symptoms to histologic diagnosis is 7 months; a laparotomy may be required to establish the diagnosis. Nutritional failure is the cause of death in over half of the patients; an additional one-quarter die of cardiac amyloid. The diarrhea of amyloid is difficult to treat [74]. Loperamide, diphenoxylate, octreotide, and tincture of opium have all been tried but with limited success. Amyloidosis can present as ischemic colitis with deposits obstructing the vessels of the lamina propria and muscularis mucosa, and lead to chronic mucosal sloughing and hemorrhage. There is a risk for gastrointestinal bleeding in patients who undergo HCT. Gastrointestinal bleeding has been associated with an inferior outcome in HCT [75].

Peripheral nervous system

Peripheral neuropathy is present in one patient in five [36]. The most common symptoms are paresthesias, muscle weakness, numbness, pain, orthostasis, urinary retention, and impotence. In one-quarter of patients, dysesthesias and distal burning accompany the peripheral neuropathy. The lower extremities are involved before the upper extremities in 90% of patients, and two-thirds of patients have autonomic symptoms. Cranial nerve involvement is rare. Carpal tunnel syndrome is seen in half of patients with amyloid peripheral neuropathy, and one-third show significant weight loss. When patients present with amyloidosis, dominant neuropathy, and a monoclonal gammopathy, consideration still needs to be given to the possibility of hereditary amyloidosis and, therefore, amyloid typing with LMD/MS is necessary.

If untreated, the neuropathy is progressive over time. Marked restriction of mobility ultimately develops in three-quarters of patients, and one-third become bedridden. There is often a significant diagnostic delay with amyloid neuropathy. Patients with a peripheral neuropathy should have serum FLC and serum and urine immunofixation studies performed. Finding a monoclonal light chain expands the differential diagnosis to include gammopathy-related neuropathy, POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, *s*kin changes), and cryoglobulinemia. Since amyloidosis preferentially causes the loss of small unmyelinated fibers, an electromyogram can be normal early in the disease course. Because amyloid is often deposited at the level of the nerve root, causing distal demyelination, the sural nerve biopsy is often negative.

Respiratory tract

Involvement of the respiratory tract is usually asymptomatic. Almost 40% of patients with amyloid deposits in the lungs have localized forms and do not have systemic amyloidosis [76]. In patients who have histologic evidence of systemic amyloidosis and lung involvement, the symptoms may be overshadowed by concomitant cardiac involvement. Even when deposits are present, gas exchange in the lungs is preserved until late in the disease. Pulmonary amyloidosis presents radiographically as an interstitial or reticulonodular infiltrate with or without pleural effusion. Bronchoscopic lung biopsy is safe and is not associated with an increased risk for bleeding. The chest X-ray is not specific, demonstrating an interstitial process that can be misinterpreted as fibrosis. In patients who have dyspnea due to interstitial lung disease, low doses of prednisone may produce symptomatic benefit. Pleural infiltration with amyloid can result in pleural effusions. Rarely, pulmonary hypertension develops in association with right-sided heart failure [77].

Hemostasis

Bleeding can be a serious complication of amyloidosis. The most common manifestation of bleeding is skin purpura. Deficiency of Factor X is seen in less than 5% of patients and is associated with hepatic involvement [78]. Normalization of Factor X levels following transplantation for hepatic amyloidosis has been reported. Bleeding associated with Factor X deficiency is generally seen only when the level falls below 25% [79]. Severe Factor X deficiency is associated with increased mortality with HCT [79]. The management of factor X deficiency prior to HCT has included splenectomy and the use of recombinant human Factor VIIa [80]. Rupture of the liver or spleen can also occur in a small fraction of patients with hepatosplenic AL-amyloidosis.

Rarely, thromboembolic disease (TED) is observed in patients with AL-amyloidosis [81]. In a single-center series of 40 patients with AL-amyloidosis and TED, thromboembolism was seen more than 1 month following the diagnosis of AL-amyloidosis in half of the patients. Twenty-nine of the 40 events were venous and 11 arterial. Risk factors for thrombosis included nephrotic syndrome, immobilization, tobacco use, heart failure, and disseminated intravascular coagulation. Five of the 40 patients had activated protein C resistance. The mortality associated with thromboembolism was 20%; 45% of the patients died within 1 year of the thrombotic event.

Prognosis and eligibility for HCT at diagnosis

Unlike multiple myeloma, the organ damage, morbidity, and mortality in AL-amyloidosis are due to the direct effects of the toxic monoclonal light chain protein, not to the proliferation of clonal plasma cells. Nonetheless, therapies that eliminate clonal plasma cells, namely those employed in myeloma, ameliorate AL-amyloidosis because they can remove the source of the toxic proteins. Survival in AL-amyloidosis depends upon rapid suppression of the synthesis of the monoclonal proteins and stabilization or recovery of heart function because the majority of patients die of complications of cardiac dysfunction. Most commonly, cardiac deaths in patients with AL-amyloidosis are the result of congestive cardiomyopathy or sudden death caused by arrhythmias or pulseless electrical activity [82]. The most important prognostic factors therefore are the presence and extent of cardiac involvement at baseline and the hematologic response to therapy, now defined by the serum FLCs [21]. Cardiac biomarker staging and standard echocardiography are useful in assessing patients with AL-amyloidosis with regard to their suitability for HCT. In the early stages of cardiac amyloid, relaxation is abnormal, and NT-proBNP and troponin levels are minimally abnormal, whereas in advanced cardiac amyloid, there is restricted filling with a shortened deceleration time, and both NT-proBNP and troponin levels can be markedly elevated.

Approximately one-quarter to one-third of newly diagnosed AL-amyloidosis patients are eligible for risk-adapted melphalan with HCT; only about one-sixth are eligible for HCT with 200mg/m^2 of melphalan [19]. Eligibility criteria for HCT usually include adequate performance status and adequate cardiac, pulmonary, and hepatic function. Patients with stage I or II cardiac involvement can do well with HCT but stage III patients tend to have a higher risk of death in the first year post-HCT. At some centers, the presence of orthostatic hypotension is an exclusion criterion for HCT, but standing systolic blood pressures greater than 90mmHg at baseline are usually deemed adequate for HCT despite orthostatic changes [18]. An elevated creatinine level has an important impact on the morbidity of HCT, and consideration of melphalan dose reduction to 140 or 100mg/m^2 must be given to patients with renal insufficiency or on dialysis [17]. Age-related criteria may play a role in specific clinical trials but, as with other diagnoses for which HCT is performed, biologic and not chronologic age may be a consideration.

We recommend that at diagnosis patients be stratified according to the extent of cardiac damage and prioritized for appropriate investigational approaches. Stratification is most widely achieved, particularly in clinical trials, by employing the cardiac biomarkers NT-proBNP and troponin and the tripartite cardiac staging system defined in the last decade [65]. Patients with stage III cardiac amyloid represent up to 25% of those seen at tertiary centers and, provided that patient age, clonal cytogenetics, and comorbidities allow, patients with advanced cardiac disease should be considered for orthotopic heart transplantation [21]. The degree of infiltration of the marrow with plasma cells should not determine eligibility provided that the patient has AL-amyloidosis and the cytogenetics and FISH show standard risk plasma cell disease [83]. Although clinical trial data supporting our view are limited, we believe that the novel agents currently available to treat plasma cell diseases can be effective in such patients after listing for heart transplant while awaiting a donor organ, and also after orthotopic heart transplant when HCT may be useful as well [84,85].

Therapy

Efficacy and end-points

We developed and validated the current categories of hematologic response based on changes in the free light chain measurements after therapy (Figure 60.3); patients achieving complete hematologic

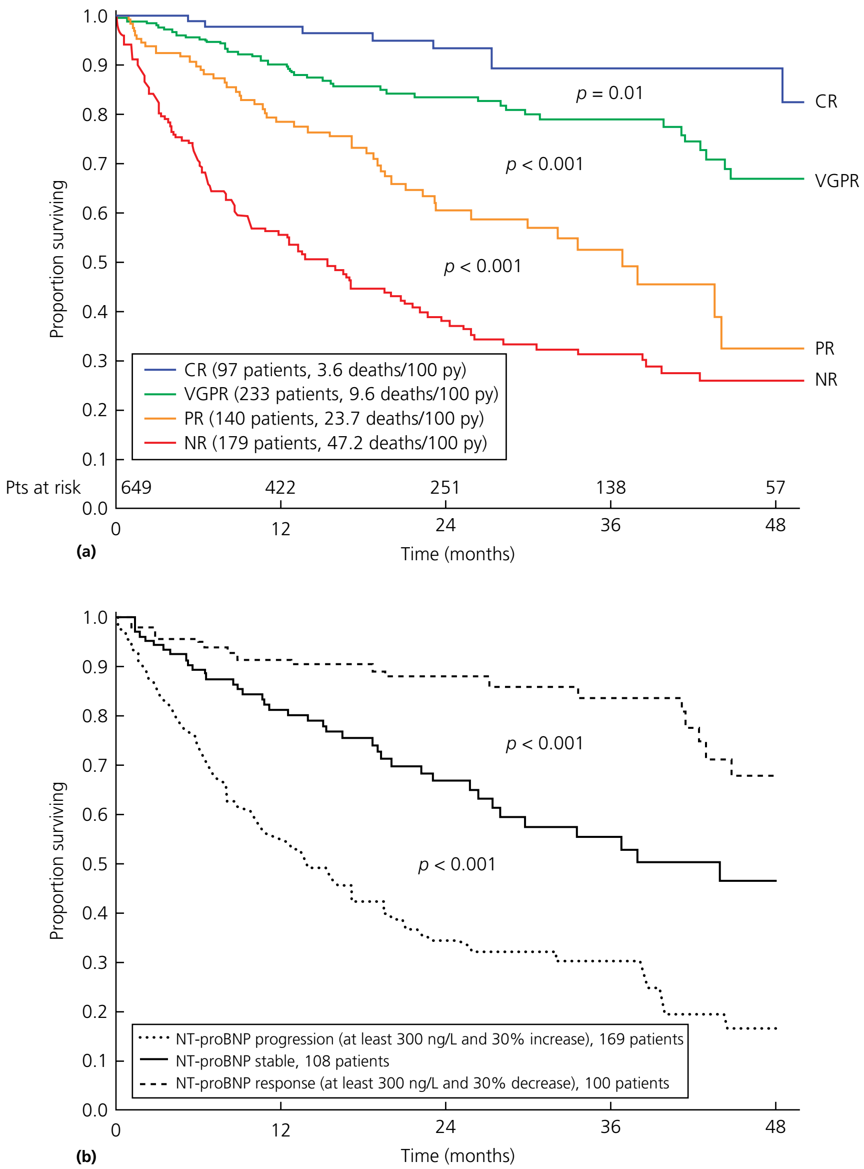

Figure 60.3 Landmark analyses of overall survival in AL patients [21]. (a) Patients in this international case series from seven centers were analyzed for survival at 3 months after beginning therapy based on metrics for hematologic response assessed at 6 months. In this series, 43.6% received oral melphalan and dexamethasone, 11.4% stem-cell transplant, 22% IMID-based therapy, and 3% bortezomib and dexamethasone. Response criteria are CR (immunofixation negative and FLC normal); VGPR [very good partial reduction; reduction in the difference between iFLC and uninvolved FLC (dFLC) to less than 40mg/L); PR (partial reduction; reduction in the dFLC by >50%); and NR (no response; less than PR). (b) Staging cardiac biomarkers were available for 53% (432/816) and 24% were stage 1 (both NT-proBNP ≤332ng/L and cTnT ≤0.035ng/mL or cTnI ≤0.1ng/mL), 52% stage 2 (either NT-proBNP >332ng/L or cTnT >0.035ng/mL or cTnI >0.1ng/mL), and 24% stage 3 (both NT-proBNP >332ng/L and cTnT >0.035ng/mL or cTnI >0.1ng/mL). In these survival curves, results for 377 patients with baseline NT-proBNP ≥650ng/L are shown according to NT-proBNP response or progression at 6 months.

response have the best survival [21]. However, although hematologic response is a key factor in prolonging survival, patients who have advanced cardiac damage at diagnosis are at high risk of sudden cardiac death and often cannot be rescued even by effective anti-plasma cell therapy [82]. Furthermore, in AL-amyloidosis, unlike myeloma, patients achieving a partial hematologic response often require additional therapy (or disease control?) to derive significant clinical benefit because ongoing light chain production may result in further organ damage. Similarly, and importantly unlike myeloma, stable clonal disease is not a benign category of response in AL-amyloidosis because of the risk of progression of organ damage. When evaluating overall response to therapy then, a partial hematologic response needs to be viewed in conjunction with organ response, and such patients must be followed closely for evidence of progression of organ damage. Patients with stable hematologic disease, that is, no response after initial therapy or after HCT, usually have short survivals.

The only effective therapeutic approach to systemic AL-amyloidosis remains reduction of amyloid-forming FLCs while providing best supportive care. Treatments that gradually reduce FLCs are likely to be ineffective because progression of amyloid organ disease continues. The FLC assay provides a direct quantitative measure of the fibril-precursor protein and of response when used serially during the course of therapy. In addition, the cardiac biomarkers, particularly the NT-proBNP, provide practitioners with an objective measure of cardiac stress. The FLC assay has significantly changed the way in which patients with AL-amyloidosis are monitored during therapy. In a prospective phase II trial using HCT and post-HCT consolidation, patients achieving a normal serum FLC κ-to-λ ratio at 3 months post-HCT had significantly better overall and progression-free survival (PFS) [19]. Furthermore, the recently updated hematologic response categories are based on FLC responses (Figure 60.3) [21]. For the 15% of patients with AL-amyloidosis and normal FLCs or dFLCs ≤40mg/L at baseline, standard criteria of response used in myeloma are available. M-proteins >500mg/dL by electrophoresis are generally considered as assessable for response, and serum and urine immunofixation identify the monoclonal component in a high proportion of patients; in such cases, the full range of newly defined FLC response categories would not be available. The use of the new FLC response criteria on clinical trials can limit accrual but the criteria have been validated and, therefore, may prove useful in registration trials of new agents.

In AL-amyloidosis, hematologic response to treatment predicts overall survival [21]. A complete hematologic response requires that, at evaluation after therapy, evidence of the monoclonal protein be absent. The serum and urine immunofixation studies must not show the baseline light chain protein, the levels and ratio of the serum free light chains should normalize, and bone marrow plasma cells should be normal in number without evidence of light chain restriction. Criteria for assessing organ responses have been defined and are in widespread use, and recently biomarker-based criteria were validated for cardiac responses (Table 60.2, Figure 60.3) [21]. Prior to the use of the FLC assay, it was difficult to gauge hematologic response and titrate therapy, although we knew that organ responses occurred frequently in patients with hematologic responses (Figure 60.4). The serologic markers of clonal disease were often difficult to interpret, particularly the urine immunofixation in the setting of evolving renal insufficiency. Also, because the improvement of amyloid organ damage lags the reduction in fibril-precursor protein, clinical correlation was not useful for assessing the need for continued therapy. Integration of the quantitative FLC assay into clinical practice allows the titration of therapy in anticipation of response before evidence of organ improvement may be available. However, and despite this advance, we do not yet have a test that can tell us the threshold below which the pathologic FLCs must be reduced (short of a hematologic complete response) in order to maximize the likelihood of stopping the disease process, and evolving renal insufficiency can also confound interpretation of the FLC assay, leading to a need for marrow biopsies to confirm or assess presumed responses or hematologic status. In the current roster of response categories, the very good partial response (VGPR) provides some help in this regard since it has been validated with respect to survival. Nevertheless, in clinical practice, we continue to follow markers of organ disease such as NT-proBNP and 24-hour proteinuria to make the determination of organ response, but the lag time must be appreciated. The major end-points of clinical research in systemic AL-amyloidosis remain hematologic response, particularly the complete hematologic response rate, organ response, and progression-free and overall survival [86].

Table 60.2 Organ response and progression criteria [21,117]

Organ	Response	Progression
Heart	NT-proBNP response (>30% and >300 ng/L decrease in patients with baseline NT-proBNP ≥650 ng/L) *or* NYHA class response (≥2 class decrease in subjects with baseline NYHA class 3 or 4)	NT-proBNP progression (>30% and >300 ng/L increase)[a] OR cTn progression (≥33% increase) *or* Ejection fraction progression (≥10% decrease)
Kidney	50% decrease (at least 0.5 g/day) of 24-h urine protein (urine protein must be >0.5 g/day pretreatment). Creatinine and creatinine clearance must not worsen by 25% over baseline.	50% increase (at least 1 g/day) of 24-h urine protein to >1 g/day or 25% worsening of serum creatinine or creatinine clearance[a]
Liver	50% decrease in abnormal alkaline phosphatase value Decrease in liver size radiographically at least 2 cm	50% increase of alkaline phosphatase above the lowest value
Peripheral nervous system	Improvement in electromyogram nerve conduction velocity (rare)	Progressive neuropathy by electromyography or nerve conduction velocity

[a] Patients with progressively worsening renal function cannot be scored for NT-proBNP progression.

Overview

Therapy for systemic AL-amyloidosis has undergone a remarkable transformation over the past four decades. Because colchicine was useful in treating patients with familial Mediterranean fever (about one-third of whom acquire "secondary" amyloidosis due to SAA protein), it was used in the 1970s to treat patients with AL-amyloidosis for whom no standard effective therapy existed [87]. Its use was not debunked until the 1990s when treatment arms containing colchicine were shown to be ineffective in phase III trials, the same trials in which oral melphalan and prednisone (MP) was shown to prolong median survival from 8 to 18 months [88,89]. The most significant side-effects of melphalan were and remain myelotoxicity and myelodysplasia. In patients who survived for more than 3.5 years, there was a 20% risk of myelodysplasia, often leading to secondary leukemia [82,90]. Approximately 5% of patients treated with alkylating agents survived for 10 years or more [91]. These long-term survivors were predominantly patients without symptomatic cardiac involvement or peripheral neuropathy who had relatively normal renal function.

By the late 1990s, oral MP had become the standard treatment for patients with AL-amyloidosis. At that time, and not without controversy, high-dose melphalan with HCT was shown in phase III trials to provide a survival benefit for patients with multiple myeloma [92]. With the high hematologic response rate noted in myeloma, phase II trials for HCT in AL-amyloidosis began. Early trials were characterized by high hematologic and organ response rates, and regression of amyloid in patients achieving hematologic complete responses (Figure 60.4). The complete response rates in these early phase II trials of HCT in AL-amyloidosis were 5–10 times higher than those seen with oral MP [15]. However, these trials also had excessive treatment-related mortality (TRM) due to sudden cardiac death, intractable hypotension, and gastrointestinal bleeding [70]. The 100-day mortality ranged from 20 to 40%, the latter in a multicenter setting, and deaths were noted during stem-cell mobilization with granulocyte colony-stimulating factor (G-CSF) alone, an unusual happenstance [93]. In the largest series ($n = 421$, covering the period 1994–2008), the overall 100-day mortality with HCT was 11.4% but for those undergoing HCT during 2003–2008 it had been lowered to 5.6% [94].

The first decade of the second millennium ushered in the era of novel agents such as thalidomide, lenalidomide, and bortezomib, all

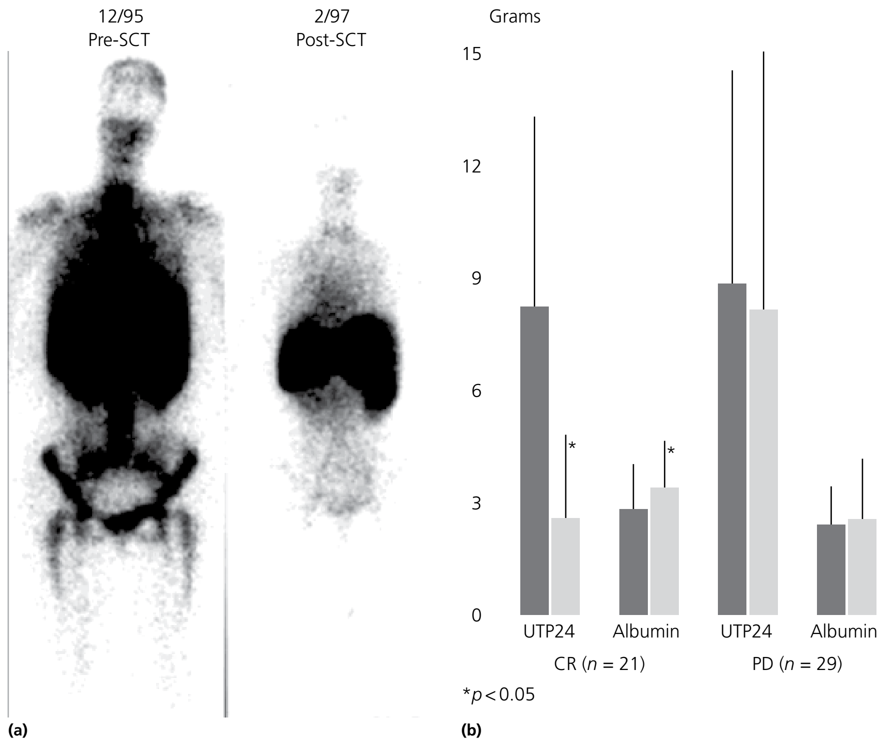

Figure 60.4 Responses of amyloid organ involvement to HCT. (a) Scintiscans employing iodine-131-labeled serum amyloid P (SAP). The black areas show uptake consistent with amyloid deposits that are extensive pre-HCT and markedly improved 14 months later. Source: reproduced with permission of Dr. Philip Hawkins. (b) Responses in 50 consecutive AL patients spilling more than 1g/day of albumin in the urine. Patients who achieved a complete response (CR, left panels) had significantly diminished daily albuminuria (UTP24) and increased serum albumin levels 1 year post-HCT ($p < 0.05$ by paired *t*-test). Those with persistent disease (PD; right panels) were basically unchanged. Mean values are shown and the whisker lines represent the standard deviations. Source: adapted from Dember et al. 2001 Ann Intern Med, 134: 746–753 [130].

of which are now approved for use in myeloma. A combination of the first of these agents, thalidomide, with MP (MPT) was compared at the phase III level with both MP and intermediate-dose melphalan (MEL) with HCT in the treatment of myeloma (MPT vs. MP vs. MEL 100), and MPT was shown to be superior [95]. Subsequently, bortezomib (Velcade) with MP (MPV) and MP (MPV vs. MP) were compared at the phase III level and MPV was shown to confer both response and overall survival advantages [96]. At last the threshold had been passed: a combination of agents had superseded MP for the treatment of myeloma patients not undergoing HCT. Notably, in AL-amyloidosis, phase II trials of dexamethasone combined in one instance with interferon-alpha and in another with oral melphalan, also showed high partial and complete response rates [97,98]. Indeed, oral melphalan and dexamethasone (MDex) became a standard therapy in AL-amyloidosis for non-transplant candidates because of its effectiveness and convenience (one 4-day course per month), despite the risk of myelodysplasia and secondary leukemia [82].

The first novel agent to be investigated in relapsed AL-amyloidosis, thalidomide, was poorly tolerated at high doses but in combination with dexamethasone in more modest doses showed efficacy [99]. The combination of oral cyclophosphamide, thalidomide and dexamethasone (CTD) showed promise in the relapsed setting [100]. In phase II trials, full-dose lenalidomide had significant toxicity, requiring dose reductions or discontinuation, and was better tolerated at 15mg/day in combination with weekly dexamethasone (LenDex), with hematologic response rates of 40–50% [101]. In recent reports on over 100 patients with relapsed AL-amyloidosis treated with LenDex, there was a 52% hematologic response rate with 16% CR, median OS of about 2 years, and, in those achieving CR, PFS of over 3 years [102]. Phase I/II studies combining LenDex with oral melphalan or cyclophosphamide had response rates not substantially different from those seen with MDex [103]. In a phase II study of pomalidomide with weekly dexamethasone (PomDex), over one-third of heavily pretreated relapsed AL-amyloidosis patients achieved a hematologic response by 6 months of treatment, highlighting the promise of this potent immunomodulatory drug (IMID) [104]. A notable confounding aspect of IMID therapy in AL-amyloidosis, however, is a rise in cardiac biomarkers that does not correlate with hematologic progression, making the use of IMIDs in AL-amyloidosis challenging [105]. Despite that complication, the IMIDs remain an active class of drugs in AL-amyloidosis.

Bortezomib is the most active and most useful of the novel agents in the treatment of AL-amyloidosis. Its safety and efficacy as a single agent in relapsed AL-amyloidosis were evaluated in a phase I/II study of 70 patients [106]. The maximum tolerated dose was not reached and evaluation of intravenous dosing at both 1.3mg/m^2 on the standard schedule (twice weekly, BIW) and 1.6mg/m^2 when given once weekly (QW) for 4 of 5 weeks was completed on the phase II level. The most common side effects were gastrointestinal with ≥grade 3 vomiting and diarrhea in five patients (prophylaxis with loperamide and granisetron was routinely used). In the QW cohort there were no instances of ≥grade 3 peripheral neuropathy (PN) and no discontinuations due to PN. Hematologic response and CR rates were the highest ever reported for a single agent: 69% with 38% CR QW, 67% with 24% CR BIW ($n = 34$), and 39% with

11% CR at lower doses. PFS at 1 year exceeded 75% and OS 90%. Renal responses were seen in 14/49 (29%), and objective cardiac responses in 5/39 patients (13%). Similar efficacy was seen in a retrospective series of 94 patients (81% previously treated) receiving bortezomib BIW and dexamethasone. There was a 71% hematologic response rate with 25% CR, a median time to progression of 25 months and 1-year survival of 75% [107]. Recently, use of the combination of oral cyclophosphamide, bortezomib and dexamethasone (CyBorD) for newly diagnosed patients with AL-amyloidosis has spread rapidly; it is particularly effective at achieving prompt reductions in the pathologic FLCs, although the durability of responses remains under study [108].

We are in a new era in the treatment of clonal plasma cell diseases. The integration of traditional therapies and novel agents continues to be a complex process. Phase II trials in AL-amyloidosis using a variety of combinations of traditional and novel agents have produced response rates similar to those seen with MDex or with HCT alone. Currently, there is no standard therapy for newly diagnosed patients who are not transplant candidates. In this new era, major differences between myeloma and AL-amyloidosis, as suggested above with respect to response categories, continue to be delineated. For instance, high-risk myeloma is defined based on the genetics of the clonal disease whereas high-risk AL-amyloidosis is defined based on the extent of cardiac involvement. Also, with respect to the role of HCT, in myeloma HCT is being challenged by the high response rates and prolonged disease control associated with maintenance or continuous therapy, despite the numerous phase III trials showing an overall survival advantage associated with HCT, whereas in AL-amyloidosis the uses of HCT are expanding as a platform for initial treatment combining risk-adapted melphalan dosing with post-HCT consolidation, after a response to initial treatment with regimens such as CyBorD, and as second-line therapy after a sub-optimal response to initial treatment. Although we now can distinguish to some extent front-line and second-line options for AL-amyloidosis patients, there is as yet no consensus on how to combine, sequence, or customize traditional and novel approaches. Also, just as there is no standard therapy for newly diagnosed patients who are not HCT candidates, there is no standard therapy for patients who do not respond to, or relapse after, initial therapy. The numerous phase II trials that are ongoing will inform us on the activity of new agents as single agents and in combination. However, phase III trials such as the one phase III trial opened for relapsed AL-amyloidosis patients (a global registration trial for the novel oral proteasome inhibitor MLN9708, ixazomib) are needed to define new standards of care. It is clear that MP is no longer standard therapy and, although the clinical options are in flux, there are clearly plenty of them. Also, just as MP is no longer a standard therapy for AL-amyloidosis, HCT for AL-amyloidosis is not investigational. The latter is a particularly important point. A case–cohort analysis has shown a survival advantage in AL-amyloidosis for good-performance status patients treated with HCT, and a second study has shown that the quality of life improves significantly in patients who respond to HCT [109,110].

Hematopoietic stem-cell transplantation for AL-amyloidosis

The dose-intensive regimens used to treat patients with AL-amyloidosis have been melphalan based, and the experience parallels that in myeloma. Melphalan alone is preferred to melphalan plus total body irradiation. In the mid-1990s, phase II trials were performed giving patients with AL-amyloidosis dose-intensive intravenous melphalan and autologous HCT [15,70]. Investigators at numerous centers documented the effectiveness of HCT in two-thirds of surviving patients, and SAP scintiscans demonstrated resorption or stabilization of deposits after the clonal plasma cells were reduced or eliminated [111]. The experience with HCT was initially controversial because of TRM. Therefore, refinement of patient selection became a priority. The extent of amyloid organ involvement clearly accounted for much of the TRM. The causes of TRM included cardiac arrhythmias, sepsis, intractable hypotension, gastrointestinal bleeding, and multiorgan failure. Adverse events during HCT occurred more frequently in patients with AL-amyloidosis than in those who received HCT for other indications. Although it is difficult to distinguish amyloid-related from treatment-related toxicities, the frequency and grade of strictly defined treatment-related toxicities appear to be a function of the dose of intravenous melphalan, as indicated by the lower-grade toxicities experienced by HCT patients with AL-amyloidosis treated with 100 as opposed to 200mg/m^2 of melphalan [15,70]. Of particular note, the gastrointestinal toxicity with 200mg/m^2 of melphalan is striking, as are the higher rates of edema and bleeding. It is reasonable to conclude that amyloidosis confers on HCT patients an increased risk; however, the toxicities per se are regimen related, and are amenable to clinical management by patient selection and dose reduction (risk-adapted melphalan dosing).

In a series of 270 patients transplanted at the Mayo Clinic for AL-amyloidosis, melphalan dosing was risk adapted [112]. Two-thirds of the patients received melphalan at 200mg/m^2, over 80% had one or two organ systems involved, and the overall TRM was 11%. In a proportional hazards model, predictors of outcome included number of organ systems affected and the baseline NT-proBNP level (Figure 60.5). Patients achieving a complete or partial response had significantly better survival than those with no response (median survival <12 months). The hematologic complete response rate with risk-adapted melphalan dosing was 33%. In a series of 421 patients transplanted at Boston Medical Center between July 1994 and December 2008, melphalan dosing was risk adapted, and the TRM was 11.4% overall and 5.6% in the last 5 years [94]. The median OS and event-free survival (EFS) post-HCT were 6.3 and 2.6 years, respectively (Figure 60.5). On an intent-to-treat basis, the hematologic CR rate at 1 year post-HCT was 34% [145 of 421; 19% of patients (n = 81) did not survive for 1 year to be evaluated]. CR was associated with median OS and EFS of 13.2 and 8.3 years, respectively. Organ responses occurred in almost 80% of patients achieving CR and 50% of those surviving to 1 year without achieving CR.

In a report from the Center for International Blood and Marrow Transplant Research, a series of 107 patients from 48 transplant centers was described [113]. The 30-day TRM was 18% and median PFS 4 years. The key predictor of survival was the experience of physicians and caregivers at the transplant center. In a multicenter phase II trial conducted by the Eastern Cooperative Oncology Group, the TRM was 10%, suggesting that treatment-related complications need not occur at a higher rate in the multicenter setting [114]. In a series of 92 patients transplanted in the United Kingdom over a 10-year period, the overall TRM was 23%, but it was only 13% over the second half of that period [111]. On multivariate analysis, TRM was associated with the number of major organ systems involved, cardiac involvement, age, performance status, and albumin level. More than 80% of patients had a greater than 50% reduction of the pathologic FLC, and at 1 year post HCT, the hematologic complete response rate was 21% by intent-to-treat (19 of 92)

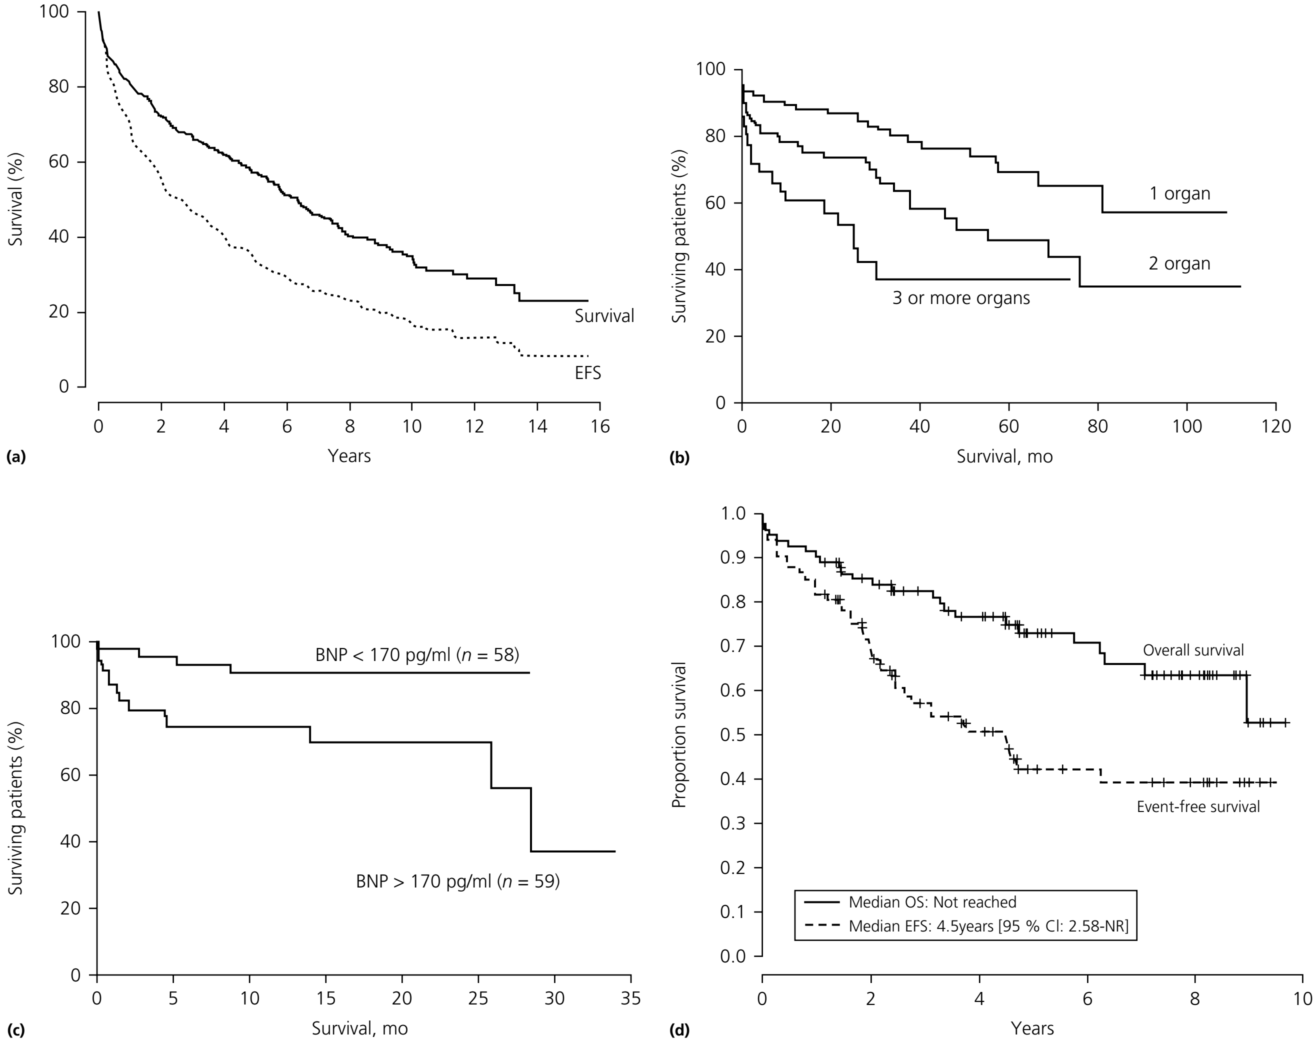

Figure 60.5 Survival after HCT [94,112,128]. These survival curves describe outcomes in (a) 421 patients transplanted at Boston Medical Center between July 1994 and December 2008 with median OS and PFS of 6.3 and 2.6 years; (b and c) 270 patients transplanted at the Mayo Clinic showing the impact of number of organs involved and NT-proBNP on survival; and (d) 83 patients transplanted at the Memorial Sloan-Kettering Cancer Center between 2002 and 2011 in phase II trials with risk-adapted melphalan dosing, HCT and adjuvant therapy for those not achieving CR with HCT; with median follow up of 5.1 years, median OS is not reached and median EFS is 4.5 years.

and 36% in evaluable patients. At 18 months post-HCT, the organ response rate was 48%. Whole-body amyloid load by SAP scintigraphy was reduced in 65% of patients evaluated pre- and post-HCT. The median survival was 5.3 years.

In a large single-center randomized prospective phase II clinical trial, 100 patients were stratified based on organ involvement and time from diagnosis, and then randomized to initial HCT or HCT after two cycles of MP [115]. The 100-day TRM was 20%, including 12% of patients who died in association with stem-cell mobilization. There were no significant differences between the two arms with respect to OS at a median of 4 years follow-up. At 5 years post-HCT, the OS was 50% for immediate and 39% for delayed HCT. The CR rates were 21 and 17%, respectively, and 42% of patients achieved an organ response at 1 year. In this trial, fewer patients randomized to initial oral therapy received HCT because progression of disease rendered them ineligible for HCT. This affected patients with cardiac involvement disproportionately. Newly diagnosed untreated patients with AL-amyloidosis eligible for HCT did not benefit from two cycles of MP. The number of organ systems affected and the presence of cardiac involvement were predictors of outcome.. For patients with one or two major organ systems affected (heart, kidneys, liver/gastrointestinal tract, and peripheral nervous system), and for those without cardiac involvement, median survival had not been reached at a median of 4 years' follow-up. For the others, median survivals were 9.3 and 5.2 months for patients with more than two organs involved, and 9.6 and 4.8 months for cardiac patients. This trial demonstrated that HCT could be safely applied to patients with AL-amyloidosis who do not have more than two symptomatic organ systems involved or advanced cardiac amyloid characterized by recurrent pleural effusions, cardiac syncope, or symptomatic arrhythmias, and made clear that the other patients are at a high risk of dying in the peri-transplant period. French investigators conducted a randomized prospective multicenter phase III trial in which stem-cell transplant with high-dose melphalan was compared with MDex given continuously for up to 18 months [116]. In the HCT group, there was a 44% early failure rate due largely to treatment-related deaths and progression of disease. TRM was 24%. Analysis of outcomes between the groups demonstrated a center effect in that patients treated at the majority of centers (27 of 29) had far better survival if they received oral therapy ($p < 0.01$), whereas patients in the two centers in which the largest fraction of HCT was performed had a trend to better survival with HCT. Median survival overall was 48 months for HCT and 58 months for MDex. Comparisons of response rates and survival between those alive at 6 months after receiving their assigned treatment showed no difference between groups. For both groups, the hematologic response rates were 65%. The organ response rate was higher in the HCT group (52% vs. 40%). Surprisingly, no cases of myelodysplasia were reported in the MDex group. Despite the apparent center effect and the need to be cautious in interpreting results with such a high TRM, this phase III trial did not define a standard initial therapy for systemic AL-amyloidosis.

Viewing HCT as a treatment platform, we conducted two phase II trials for newly diagnosed AL-amyloidosis patients combining risk-adapted melphalan dosing and HCT and incorporated consolidation for patients who had not achieved CR following HCT. In the first trial, we used post-HCT thalidomide and dexamethasone (TD), and in the second, bortezomib and dexamethasone (BD) [19,20]. In these trials, we showed that HCT for AL-amyloidosis can be performed with a low TRM using risk-adapted melphalan at 100, 140 or 200mg/m^2 based on age, renal function, and cardiac involvement, and that post-HCT consolidation significantly and safely improved hematologic response rates [19,20]. In the first trial, TRM was 4.4% (2 of 45), with both deaths in patients with cardiac involvement; there were no deaths during consolidation. At 3 months post-HCT, the hematologic response rate was 63% with 21% CR and no difference in OS or CR rates based on the dose of melphalan. Thirty-one patients received post-HCT TD, but only 52% ($n = 16$) completed all 9 months as planned, with 16 and 32% discontinuing for progression of disease and toxicity, respectively. The median nightly dose of thalidomide was 150mg (range 50–200mg), and the majority of patients received one or two dexamethasone pulses per month. Despite the high discontinuation rate, 42% of patients receiving consolidation had an improved hematologic response at 1 year post-HCT. The overall response rate at 1 year was 78% [95% confidence interval (CI) 65–90%], with 39% achieving a complete hematologic response (95% CI 24–53%). By intent-to-treat, these rates were 71% (95% CI 57–84%) and 36% (95% CI 21–50%), respectively, again with no significant difference seen based on melphalan dosing. For patients with cardiac involvement, estimates of 1- and 2-year OS were 63% at both times (95% CI 34–91%). Median PFS was 40 months with 74% (95% CI 61–87%) of patients remaining progression free at 2 years. In univariate analysis, the baseline characteristics associated with OS were the number of organ systems involved and the baseline troponin level. In multivariate analysis, having a normal serum FLC kappa-to-lambda ratio at 3 months post-HCT and achieving a hematologic response at 12 months post-HCT were associated with improved OS and PFS.

In the second trial, we used BD as consolidation after risk-adapted melphalan HCT in 40 untreated AL-amyloidosis patients with renal (70%), cardiac (65%), liver/gastrointestinal (15%), or nervous system (13%) involvement.. Four patients with advanced cardiac AL-amyloidosis died within 100 days of SCT (10% TRM). Survival at 12 and 24 months was 88 and 82%, respectively, overall and 81 and 72%, respectively, in patients with cardiac AL-amyloidosis. At 3 months post-HCT, 45% had a hematologic response (≥PR), including 27% CR. Twenty-three patients received consolidation and in 86% the response improved, all within one cycle. At 12 and 24 months, 79 and 60%, respectively, had ≥PR and 58 and 40%, respectively, had CR. Organ responses occurred in 55 and 70% at 12 and 24 months, respectively. Eight patients relapsed but only one patient with serologic relapse had worsening organ function. In both of these trials, unlike the studies reported above, hematologic response criteria were strictly FLC based [21,86,117]. The overall TRM was 7%, and the CR rate following SCT was 24%, increasing to 48% with post-SCT adjuvant therapy. The CR rates increased at 1 year compared with 3 months post-SCT to 36% with TD and to 60% with BD. With a median follow-up of 5.1 years, EFS is 4.5 years and median OS has not been reached (Figure 60.5). These results indicate that risk-adapted melphalan dosing with HCT and consolidation is an effective initial treatment strategy for patients with AL-amyloidosis and results in low TRM, high CR rates, maintained organ improvement, and long survival.

Mobilization and immune reconstitution

Mobilized hematopoietic stem cells collected by apheresis of blood have provided the marrow rescue products for patients with AL-amyloidosis receiving HCT. In an early trial, two-thirds of patients had amyloid identified in the bone marrow, but this did not impair mobilization [15]. Contamination with clonotypic plasma cells has been demonstrated in these stem-cell products collected after growth factor priming, and CD34$^+$ cell selection is possible with adequate yields, but the effect on the disease course of having a positively selected apheresis product remains unknown [118]. Currently, G-CSF mobilization is used at the majority of centers transplanting AL-amyloidosis patients regularly, although G-CSF combined with plerixafor has been shown to enhance CD34$^+$ cell mobilization and collection in myeloma and even has single-agent activity in that regard [119,120]. The mechanism of action of G-CSF mobilization in the marrow stem-cell niche has been the subject of intensive study over the past decade and the data support a role for a "stress response" in which mediators of the sympathetic nervous system cause alterations in the CXCR4–CXCL12 axis, resulting in the release and egress of CD34$^+$ cells into the marrow sinusoids and peripheral blood [121,122]. In order to evaluate this association clinically, we collected 24-hour urine samples prior to G-CSF mobilization from 40 AL-amyloidosis patients enrolled in a phase II clinical trial using risk-adapted melphalan dosing and analyzed them for epinephrine, norepinephrine, and dopamine excretion. Baseline urinary excretion of epinephrine and dopamine correlated with the total CD34$^+$ cells per kilogram collected (0.33, $p = 0.005$; and 0.47, $p = 0.05$, respectively). An optimal collection defined as $\geq 5 \times 10^6$ CD34$^+$ cells in two collections was associated with baseline epinephrine ($p = 0.02$) and dopamine ($p = 0.05$) levels [123]. These preliminary data may help guide the addition of plerixafor to G-CSF for mobilization in AL-amyloidosis patients.

Given the impaired visceral reserve, vasculopathy, and coagulopathies associated with AL-amyloidosis, it was predictable that treatment-related toxicity would be more prominent in these patients. It was not expected, however, that there would be significant toxicity associated with the mobilization and collection of blood stem cells. At Boston Medical Center, of 312 patients who underwent stem-cell mobilization with cytokines from July 1994 to June 2002, 13 died and 22 had complications of mobilization that prevented them from undergoing HCT [124]. Deaths have been reported during the mobilization of patients with symptomatic cardiac amyloid and multisystem disease [115]. Excessive fluid accumulation during mobilization has been shown to be an independent predictor of first-year mortality post-HCT [68]. In a retrospective study of 126 patients who underwent HCT at the Mayo Clinic between July 1997 and June 2003, body weight increased more than 2.0% during mobilization in over half of patients. Those with >2.0% weight gain had more proteinuria, more organ systems involved, lower serum albumin, and greater diuretic dependence. They also had significantly higher first-year mortality (33.9% vs. 9.8%, $p = 0.002$). In multivariate analysis, independent predictors of first-year mortality included weight gain, glomerular filtration rate, and septal thickness. The increase in mortality was noted despite diuresis of the excess weight prior to HCT.

Immune recovery after autologous HCT for AL-amyloidosis has been studied prospectively in a cohort of patients with AL-amyloidosis [125]. At 3 months following HCT, $CD4^+$ cells were significantly decreased and T-cell function was depressed. In contrast, $CD8^+$ cells, monocytes, natural killer cells, B-cell number, and functional activity (measured by both quantitative immunoglobulin levels and the proliferative response to staphylococcal antigen) had returned to the normal range. These outcomes are similar to those reported for patients with other hematologic diseases after autologous HCT, although the prompt recovery of humoral immunity is somewhat atypical. Opportunistic infections, including *Pneumocystis jiiroveci* pneumonia and herpes zoster, were seen within the first year post-HCT, and several deaths due to sepsis occurred between 6 and 12 months post-HCT. This experience in the year post-HCT clearly supports the use of pre-HCT trimethoprim/sulfamethoxazole or aerosolized pentamidine and post-HCT acyclovir prophylaxis.

Peri-transplant management

Cardiac complications, gastrointestinal bleeding, and multiorgan failure with hypotension have been significant causes of early mortality with HCT in AL-amyloidosis [126]. These complications usually occurred within the first 14 days of HCT; the degree to which sepsis, autonomic dysfunction, occult chronic infections, immunologic impairments, and amyloid vasculopathy contribute to these complications is unknown.

Gastrointestinal bleeding is unusual after autologous HCT in all patients, and in frequency and severity is unique to patients with AL-amyloidosis. If amyloid extensively infiltrates the submucosa of the stomach or lower gastrointestinal tract, the potential for severe mucositis with hemorrhage must be anticipated, while neuropathic compromise of the enteric plexus often results in atony, persistent post-transplant nausea, and failure to thrive. For these reasons, pre-transplant planning and peri-transplant supportive care become critical elements of the care plan. Recommendations with respect to pre- and peri-transplant management have been described in detail, and include stool guaiac testing for occult blood [17]. Pre-transplant patient evaluation should also include a detailed review of gastrointestinal signs and symptoms, endoscopic studies to define pathology when indicated by history or the presence of occult blood in stool, and a complete assessment of coagulation status. It is important to note that major gastrointestinal bleeding can present atypically; for example, as new-onset atrial fibrillation or supraventricular tachycardia. In HCT patients with known gastrointestinal amyloid, if stool guaiac results are positive, the hemoglobin should be kept above 9g/dL and platelets maintained over 50,000/μL. It is also important to keep in mind that visceral rupture (e.g., splenic rupture) can occur acutely in patients with AL-amyloidosis. Vague or atypical left-sided abdominal or shoulder pain should raise a concern about splenic hemorrhage and lead to imaging the abdomen. Splenic rupture occurring during this period has been successfully managed surgically. Other viscera, such as the esophagus or small bowel, can also perforate and present life-threatening challenges. Peri-transplant, proton pump inhibitors should be used for gastrointestinal prophylaxis and, because dose-intensive intravenous melphalan can cause delayed emesis, an antiemetic regimen combining low-dose dexamethasone, lorazepam, and ondansetron may be useful beginning the day after the infusion of the graft.

In our experience, the peri-HCT mortality rate in patients with cardiac amyloid and congestive heart failure, or with a history of cardiac arrhythmias, syncope, or recurrent pleural effusions, approaches 100%, while patients with uncomplicated or well-compensated cardiac amyloid and no other symptomatic organ involvement have a low peri-HCT mortality and 65–85% 1-year survival. In patients with dominant cardiac amyloid with minimal symptoms, preserved left ventricular function usually assures diuretic responsiveness. Maintenance of normal electrolyte levels in cardiac patients receiving diuretic therapy is an obvious requirement. In a detailed study of arrhythmia events in 24 consecutive AL-amyloidosis cardiac patients undergoing risk-adapted melphalan and SCT with continuous telemetric monitoring, the relation between number and severity of ventricular arrhythmias [ventricular tachycardia/ventricular fibrillation (VT/VF)] and baseline clinical, laboratory, and echocardiographic data were determined. All patients displayed atrial and ventricular arrhythmias and non-sustained VT was the most frequent event. In 20/24 patients therapeutic intervention for arrhythmias was required usually with low-dose β-blockers; in three patients, life-threatening arrhythmias were detected and treated. There was an inverse relation between VT/VF and cardiac output ($r = -0.72$, $p < 0.0001$), cardiac index ($r = -0.71$, $p = 0.0001$), and stroke volume ($r = -0.59$, $p = 0.0029$). There was also a relation between VT/VF and brain natriuretic peptide (BNP) before SCT ($r = 0.47$, $p = 0.019$), average BNP levels during SCT ($r = 0.62$, $p = 0.0012$), troponin I levels at diagnosis ($r = 0.47$, $p = 0.022$), and serum creatinine levels before SCT ($r = 0.62$, $p = 0.001$). It was concluded that decreased cardiac output was strongly associated with risk of significant ventricular arrhythmias and that continuous telemetric monitoring contributed to patient safety during HCT.

The mortality associated with cardiac amyloid in HCT recipients is due to sudden cardiac death and to cardiopulmonary failure, resulting in hypotension and hypoxia. Patients rarely, if ever, survive hypotensive bradycardic episodes despite the addition of appropriate medications and the use of advanced life support measures. Hemodynamically stable tachycardias, on the other hand, are frequent and tolerated. Use of β-blockade simply for control of sinus tachycardia should not be routine. Whether prophylactic pacemakers or implanted automated defibrillators may impact peri-HCT mortality in these patients remain matters for further clinical investigation.

The management of intravascular volume and hypotension is a critical aspect of care. Nephrotic syndrome causes salt avidity and hypoalbuminemia, and therefore often leads to significant edema. The risk of overdiuresis, however, may be greater than the risk of allowing some peripheral edema in the setting of clinical euvolemia. Even mild intravascular volume depletion may exacerbate nausea and emesis; therefore, twice daily orthostatic vital signs and normal saline support when indicated are recommended. Nevertheless, maintaining a diuresis concurrently with melphalan administration and graft infusion is reasonable. Since a major factor causing pulmonary and peripheral edema is hypoalbuminemia, albumin infusions should be used throughout the treatment period to maintain a serum level above 2.0g/dL. In these patients, albumin infusions can help mobilize fluid in the tissues and therefore administering albumin along with diuretics can be effective. Other supportive measures such as compression garments and/or lymphedema therapy should also be utilized in patients with peripheral edema and low blood pressure who require diuresis.

The multiorgan failure syndrome and intractable hypotension seen as a toxicity of HCT in patients with AL-amyloidosis likely reflect the limitation on visceral reserve imposed by fibril deposition. Volume depletion, bleeding, sepsis, and hypoadrenalism, followed by worsening autonomic neuropathy, are the most likely causes of hypotension post-HCT. The cellular and hormonal aspects of the syndrome remain poorly characterized. Use of morphine or fentanyl to treat mucositis can affect both blood pressure and urine output, and can complicate acyclovir prophylaxis. When renal perfusion and urine output are reduced, risk of acyclovir toxicity increases. Midodrine and fludrocortisone are useful treatments for orthostasis but do not work reliably in the transplant setting. At the time of neutrophil recovery or myeloid engraftment, it is not uncommon for patients to experience orthostasis requiring more aggressive hydration.

At the Mayo Clinic, post-HCT G-CSF is not used to support hematopoietic recovery because of the morbidity, particularly the fluid retention, associated with its use. In the series of 270 patients from that institution, median time to recovery of an absolute neutrophil count over 500/μL was 14 days, whereas in contrast the median time at other major centers was 10 days [112]. A detailed cost–benefit comparison has not been performed, but now with the availability of pegfilgrastim (Neulasta), a long-acting preparation requiring a single administration and hence minimal nursing and pharmacy costs, such a comparison would be welcome and useful [127]. Longer periods of neutropenia may result in an increased frequency of fevers requiring laboratory evaluation, empiric antibiotic use, and inadvertent side effects.

Relapse

The population of AL-amyloidosis patients living with hematologic responses and stable or improved organ function or with hematologic relapse after response to initial therapy is growing. Recently, we developed consensus definitions of relapsed and refractory disease in AL-amyloidosis. We defined relapsed disease as progression of hematologic or organ disease after a response to initial therapy, refractory hematologic disease as no response to initial therapy or stable disease despite therapy, and refractory organ disease as persistent significant organ disease causing symptoms despite prior therapy and best supportive care [86].

Data on relapse and outcomes with second-line therapy are just being reported. There are no patient series describing second HCT as salvage therapy in AL-amyloidosis. In the largest series of HCT patients (*n* = 421), at a median of 6.9 years follow-up (range 1–15.6 years), among those who achieved CR, 28% (40/145) had hematologic relapse and 40% (16/40) of relapsed patients died. In contrast, among those with maintained CR, 24% (25/105) had died. In the two phase II trials for newly diagnosed untreated AL-amyloidosis patients using risk-adapted melphalan dosing with HCT and post-HCT consolidation, 16 patients died prior to relapse and 26 relapsed by FLC criteria with a cumulative incidence of 8, 18, and 29% at 1, 2, and 3 years, respectively, while the remainder remained progression free. About 31% (8/26) of relapsed patients did not require second-line therapy, likely due to the very sensitive serum free light chain assay that detects low-level hematologic progression in the absence of organ progression. Among those who required second-line therapy, 78% (14/18) responded, including 44% (8/18) with CR. The median OS following relapse was 5 years (95% CI 2.6–5.8 years). In a retrospective study of 193 patients undergoing HCT at the Mayo Clinic between 2005 and 2009, 27 died prior to relapse, 41% (*n* = 79) relapsed and the remainder remained progression free. Among the relapsed patients, the median time to relapse was 14.4 months and hematologic progression (68%) was more common than progression of organ damage (37%). About 90% (*n* = 70) received second-line therapy with response rates of 40–55%. With a median 26 months of follow-up of survivors, the 1- and 3-year OS were 87 and 59%, respectively.

Conclusion

AL-amyloidosis remains a disease for which our tests, treatments, and knowledge continue to evolve. Survival remains the primary end-point for both patients and clinical investigators. LMD/MS is the newest tool available, allowing unequivocal typing of tissue amyloid. The FLC assay is the most important development for baseline assessment and for monitoring the course of therapy. HCT for AL-amyloidosis remains most effective in patients who are younger or have limited disease and, by combining risk-adapted melphalan dosing and HCT with novel agents such as bortezomib, the response rates, PFS and OS of patients improve over the short term. As we come to understand more fully the basis of the organ disease that amyloid-forming light chains cause, novel cytoprotective pathways may be identified and simple and effective drug treatments developed. The ideal treatment for AL-amyloidosis in the future will involve a combination of approaches aimed at eliminating the fibril-precursor light chains, inhibiting their self-assembly, and enhancing resorption of fibrillar deposits. In the future, such therapeutic combinations will continue to include HCT because of the extent to which it enhances recovery and extends the survival of patients with AL-amyloidosis.

CHAPTER 61

Autologous Hematopoietic Cell Transplantation for Breast Cancer and Germ-cell Tumors

Yago Nieto and Elizabeth J. Shpall
The University of Texas M.D. Anderson Cancer Center, Houston, TX, USA

Introduction

Autologous hematopoietic progenitor-cell support (AHPCS), derived from bone marrow or from peripheral blood progenitor cells (PBPCs), allows for the dose escalation of chemotherapy up to 10-fold, exploiting the dose–response effect of alkylators and other drugs. While AHPCS circumvents myelosuppression, extramedullary organ toxicities become dose limiting. These substantial dose increments clearly increase the antitumor activity of high-dose chemotherapy (HDC) compared with standard-dose chemotherapy (SDC), with the goal of improving patient outcome. Widespread substitution of PBPCs for bone marrow support and other improvements in patient care have increased the safety of HDC to current treatment-related mortality (TRM) rates below 5%.

Hematopoietic cell transplantation for breast cancer

Despite the advances in standard therapy, more than 50% of patients with high-risk primary breast cancer (HRPBC) and virtually all patients with metastatic breast cancer (MBC) receiving SDC experience treatment failure and ultimately die from their disease. The initial prospective phase II trials of HDC in breast cancer, dating back to the late 1980s, were followed by randomized studies in both settings. Some argued that the impressive results of the phase II trials could be explained by patient selection, staging biases, or short follow-up. Thus, controversy has surrounded HDC for breast cancer almost since its inception [1,2].

High-dose chemotherapy trials in metastatic breast cancer

Prospective HDC trials in MBC targeted in a sequential fashion patients with refractory [3,4], untreated [5], and responding disease [6–8]. It soon became clear that not only did HDC produce the highest response rates (RRs) and complete response (CR) rates ever reported in MBC, but also a consistent long-term event-free survival (EFS) rate of 10–25% in patients transplanted after response to first-line chemotherapy, which appeared unprecedented (Figure 61.1). These results triggered phase III evaluation of HDC, employing a variety of regimens, for MBC (Table 61.1).

In the Philadelphia study, Stadtmauer et al. randomized 184 patients responding to first-line therapy to receive HDC with STAMP-V [cyclophosphamide/thioTEPA (*N*-triethylenethiophosphoramide)/carboplatin] or maintenance CMF (cyclophosphamide/methotrexate/fluorouracil) for 18 months or until progression [9]. At its final update at a median follow-up of 5 years there were no differences in EFS (4% vs. 3%) or overall survival (OS) (14% vs. 13%). A significant interaction was detected between age and treatment, with young and older patients apparently benefiting from HDC and CMF, respectively. With only 45 patients in CR treated, this study was grossly underpowered to detect any meaningful difference in this subset. Strikingly, the PR to CR conversion rate was higher after CMF than after STAMP-V (9% and 6%, respectively). The low CR conversion rate in the transplant arm seemed much lower than in most HDC trials, where CR conversion rates of 20–50% were typically reported.

In the National Cancer Institute of Canada (NCIC) trial, Crump et al. randomized 224 responsive MBC patients to additional SDC or HDC with cyclophosphamide/mitoxantrone/etoposide [10]. The dropout rate in the transplant arm was 20%. Transplant-related mortality was 6%. At a median follow-up of 4 years, intent-to-treat comparisons showed significant differences in favor of transplant in EFS (median 11 vs. 8 months, $p = 0.006$), but not OS (median 24 vs. 28 months, $p = 0.4$).

In the French PÉGASE 03 study, Biron et al. randomized 180 patients with responsive tumors to receive HDC with cyclophosphamide/thioTEPA or observation [11]. The CR rate increased from 11 to 24% after HDC ($p = 0.0002$). At a median follow-up of 48 months, a significant EFS advantage was observed in favor of HDC (27% vs. 10%, $p = 0.0005$), without significant OS differences (38% vs. 30%, $p = 0.7$).

Crown et al. from the International Breast Cancer Dose Intensity Study (IBDIS) group randomized 110 patients to receive doxorubicin/docetaxel × 4, followed by either CMF × 6 or sequential high-dose cycles of ifosfamide/carboplatin/etoposide (ICE) and cyclophosphamide/thioTEPA with AHPCS [12]. The HDC arm produced higher RR (71% vs. 44%) and CR rates (29% vs. 6%). At a median follow-up of 42 months, the study was positive for its primary end-point, EFS (HDC 16% vs. SDC 9%, $p = 0.01$), with a trend for an OS advantage in the HDC arm in an intent-to-treat analysis (45% vs. 37%, $p = 0.1$).

In the PÉGASE 04 trial, Lotz et al. randomized 61 responding MBC patients to additional SDC or HDC with cyclophosphamide/mitoxantrone/melphalan [13]. In its final analysis at a median follow-up of 7.5 years, significant benefits from HDC were shown

in PFS (18.7% vs. 0%, median 12 vs. 6 months, $p < 0.005$) and OS (36.8% vs. 13.8%, median 44 vs. 19 months $p = 0.02$).

In the German Breast Cancer Dose Intensity Study (GEBDIS) group trial, Schmid et al. randomized 92 untreated MBC patients to receive adriamycin/paclitaxel × 6–9 or tandem cycles of high-dose cyclophosphamide/mitoxantrone/etoposide, 6 weeks apart with AHPCS [14]. At a median follow-up of 52 months, there were no significant differences between the high-dose and control arms in PFS (27% vs. 20%, $p = 0.5$) or OS (18% vs. 21%, $p = 0.75$).

Investigators at Duke University conducted two randomized trials with a crossover design, comparing early versus late use of HDC, using cyclophosphamide/cisplatin/BCNU [1,3-bis(2-chloroethyl)-1-nitrosourea (carmustine)] (STAMP-I). In the first trial, 100 hormone-refractory MBC patients in first CR were randomized to immediate HDC or observation with HDC at subsequent relapse [15]. At a median follow-up of 10.6 years, EFS was superior in the immediate transplant arm (26% vs. 10%, $p = 0.03$), with a median EFS of 10 versus 4 months ($p < 0.006$). Six-year OS rates were 26.5% versus 35% ($p = 0.69$), with median OS times of 2.1 versus 3.3 years ($p = 0.2$). The combined TRM from transplant in both arms was high (8.6%).

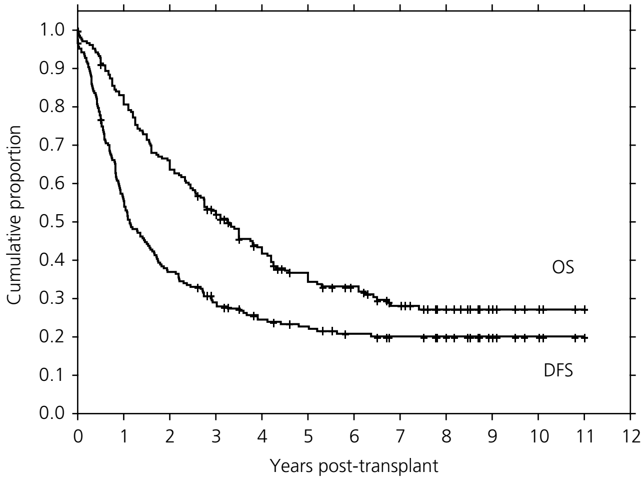

Figure 61.1 Long-term disease-free survival (DFS) and overall survival (OS) of prospective phase II trials with cyclophosphamide/cisplatin/BCNU (carmustine) (STAMP-I) as first-line therapy for MBC patients at the University of Colorado.

In the second Duke University trial, 69 patients with hormone-refractory bone-only MBC were randomized after first-line SDC to immediate HDC and radiotherapy of all bony metastases, or to radiotherapy and observation, again with HDC upon progression [16]. At a median follow-up of 8.1 years, EFS was superior in the immediate transplant arm (17% vs. 0%, $p < 0.0001$) with median EFS times of 12 versus 4 months ($p < 0.0001$). The OS rates were not significantly different between the immediate and late transplant arms (17% vs. 9%, $p = 0.1$) with median OS times of 3 versus 1.8 years. As in the other Duke trial with STAMP-I, the overall transplant TRM was high (9.7%).

In summary, a significant benefit in EFS in favor of HDC was noted in six of the eight trials, but only one study (PÉGASE 04) showed an OS advantage. The lack of a direct comparison between HDC and non-HDC arms in the two Duke crossover trials obviated OS analyses complicating their interpretation.

Berry et al. conducted a meta-analysis based on the individual patient data from six of those trials (excluding the two Duke crossover studies), involving a total of 866 patients [17]. A significant PFS benefit from HDC was detected [median 11 vs. 8 months, hazard ratio (HR) of 0.76, $p < 0.001$], with the OS differences not reaching significance (HR 0.87, $p = 0.08$). There was no detrimental effect of HDC on OS after progression (HR 1.01, $p = 0.95$).

High-dose chemotherapy in high-risk primary breast cancer (HRPBC)

The groups at Duke University [18] and the National Tumor Institute in Milan [19] pioneered the evaluation of HDC in HRPBC patients. Long-term results of Peters and colleagues at Duke University in patients with ≥10 involved (+) axillary nodes showed a 10-year EFS rate of 72% [20]. In the Milan study, Gianni et al. explored a sequential high-dose single-agent approach and reported a 57% EFS rate at median follow-up of 4 years [19].

[a] Not evaluable for a direct OS comparison, due to crossover design.

The encouraging prospective phase II data of HDC in HRPBC (Figure 61.2) prompted subsequent randomized phase III trials, which have undergone final analyses (Table 61.2). The Dutch trial by Rodenhuis et al. randomized 885 patients with ≥4+ lymph nodes to receive fluorouracil/epirubicin/cyclophosphamide (FEC) × 4 followed by one more cycle of FEC or high-dose cyclophosphamide/thioTEPA/carboplatin (CTC) [21,22]. At a median follow-up of 7 years, a trend for an EFS advantage was noticed in favor of HDC (64.3% vs. 59%, HR 0.84, $p = 0.07$), with no detectable OS differences (73% vs. 70%, $p = 0.2$). Prospectively planned subset analyses showed a substantial EFS improvement among patients with ≥10+ nodes (68% vs. 49%, $p = 0.01$). In the 4–9+ node group, EFS rates were 72% (HDC) versus 65% (SDC) ($p = 0.5$). Other subgroup analyses, which were unplanned, suggested that young patients, those with HER2 negative, or those with lower grade tumors might benefit from HDC. Specifically, patients with

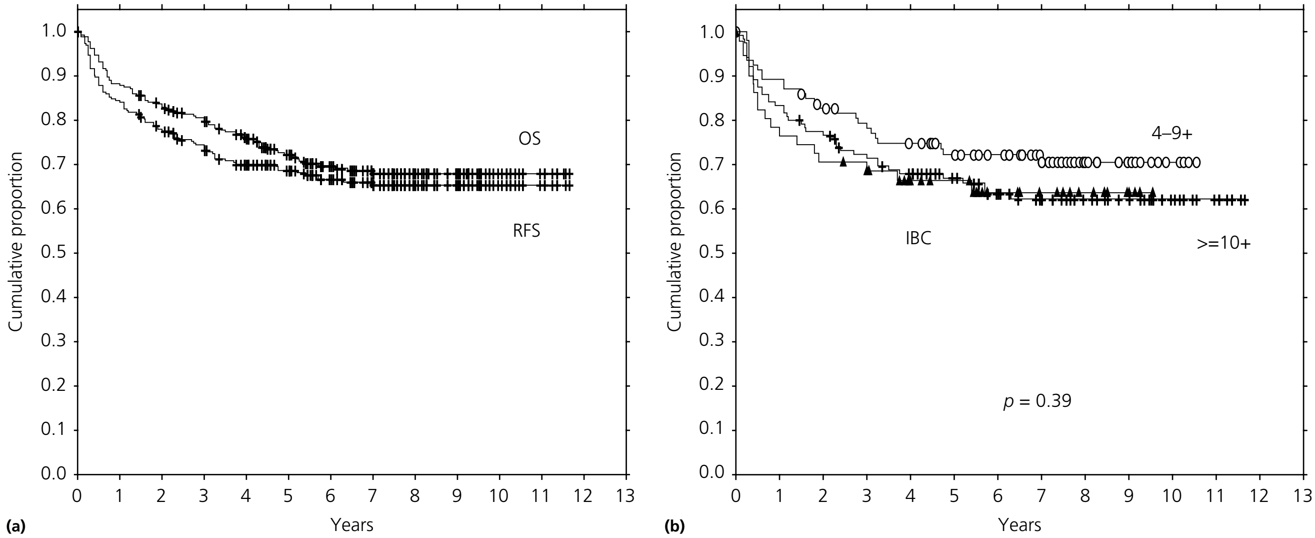

Figure 61.2 HDC for HRPBC. (a) Long-term relapse-free survival (RFS) and overall survival (OS) of 264 patients enrolled in prospective phase II trials of cyclophosphamide/cisplatin/BCNU (carmustine) (STAMP-I) at the University of Colorado, at a median follow-up of 7 years. (b) RFS in the different populations enrolled in those trials: 4–9+ nodes, ≥10+ nodes, and inflammatory breast cancer (IBC).

n, No. of patients; FU, follow-up. NWAST, Netherlands Working Party on Autologous Transplantation in Solid Tumors; CALGB, Cancer And Leukemia Group B; ECOG, Eastern Collaborative Oncology Group; SWOG, Southwest Oncology Group; SBCG, Scandinavian Breast Cancer Group; WSG, West German Study Group; IBCSG, International Breast Cancer Study Group; GABG, German Autologous Bone Marrow Transplant Group; ICCG, International Collaborative Cancer Group; JCOG, Japan Clinical Oncology Group; MDACC, M.D. Anderson Cancer Center; EBMT, European Blood and Marrow Transplant Group; CPA, cyclophosphamide; TT, thioTEPA; Cb, carboplatin; Epi, epirubicin; Mito, mitoxantrone; Mel, melphalan; Eto, etoposide; HR, hazard ratio; NR, not reported; NS, not significant; mo, months; yr, years.

HER2-negative disease (n = 621) experienced a marked benefit from HDC in EFS (72% vs. 59%, $p = 0.002$), and OS (78% vs. 71%, $p = 0.02$), with an HR for relapse decreased by about one-third after HDC.

In the Cancer and Acute Leukemia Group B (CALGB) 9082 trial, Peters et al. enrolled 785 patients with ≥10+ nodes, who received four cycles of CAF and were randomized to HDC with cyclophosphamide/cisplatin/BCNU (STAMP-I) or to one additional cycle of those drugs at intermediate doses (IDs) with G-CSF support [23]. At a median follow-up of 7.3 years, there were no significant differences between the HDC and ID arms in EFS (61% vs. 58%, $p = 0.2$) or OS (71% for both groups, $p = 0.7$). There was a 31% reduction in the number of relapses in the HDC arm, particularly among women younger than 50 years of age, which was offset by a high TRM rate of 8.1% in the HDC arm (versus 0% in the ID arm).

In the Anglo-Celtic trial, Leonard et al. randomized 605 patients with ≥4+ nodes to receive four cycles of doxorubicin followed by either high-dose cyclophosphamide/thioTEPA (CT) or CMF × 8 [24]. At a median follow-up of 6 years, there were no differences in EFS (57 and 54%, respectively, $p = 0.7$) or OS (62 and 64%, respectively, $p = 0.4$).

Tallman et al. from the Eastern Cooperative Oncology Group (ECOG) randomized 540 patients with ≥10+ nodes to receive CAF × 6, with or without high-dose CT, administered with AHPCS from bone marrow or, towards the end of the study, PBPCs [25]. At a median follow-up of 6 years, there were no significant differences between HDC and SDC in EFS (55% vs. 48%, $p = 0.1$) or OS (58% vs. 62%, $p = 0.3$).

The Southwest Oncology Group (SWOG) trial randomized 539 patients with ≥4+ nodes (92% of them with 4–9+ nodes) to receive conventional treatment with sequential dose-dense adriamycin/paclitaxel/cyclophosphamide, or Adriamycin (doxorubicin)/cyclophosphamide (AC) × 4 followed by HDC (using STAMP-V in 86% and STAMP-I in 14% of patients) [26]. At a median follow-up of 70 months, there were no differences in EFS (78% vs. 73%, $p = 0.35$) or OS (87% vs. 83%, $p = 0.4$).

Bergh et al. for the Scandinavian Breast Group randomized 525 patients with ≥8+ nodes [or ≥5+ nodes plus an estrogen receptor (ER)-negative and high S-phase fraction tumor] to receive nine cycles of individually tailored dose-intensive FEC, or conventional FEC × 3 followed by HDC with STAMP-V [27]. At a median follow-up of 5 years, there was a trend in favor of tailored FEC in EFS (51% vs. 45%, $p = 0.07$), with no significant differences in OS (60% vs. 56%, $p = 0.3$) [28]. A major problem in interpreting this study is that the control arm received higher cumulative doses of chemotherapy than the transplant arm.

In the West German Study Group (WSG), Nitz et al. randomized 403 patients with ≥10+ nodes to receive a dose-dense arm with epirubicin/cyclophosphamide (EC) × 4 followed by CMF × 6 or a transplant arm with two initial cycles of EC followed by tandem cycles of high-dose epirubicin/cyclophosphamide/thioTEPA administered 4 weeks apart with AHPCS [29]. At a median follow-up of 4 years, HDC resulted in improved EFS (60% vs. 44%, $p < 10^{-3}$) and OS (75% vs. 70%, $p = 0.02$). An unplanned retrospective analysis showed a large benefit from HDC for tumors with a basal-like phenotype [ER/PR (progesterone receptor) negativity, HER2 negativity, and basal cytokeratin positivity], with HR for relapse of 3.06 (95% CI 1.41–6.06) if receiving dose-dense chemotherapy compared with tandem HDC [30].

The Michelangelo study by Gianni et al. compared the Milan high-dose sequential single-agent approach with SDC in 382 patients with ≥4+ nodes [31]. At a median follow-up of 11 years, non-significant differences in favor of the high-dose arm in EFS (52% vs. 44%) and OS (60% vs. 51%) were noted.

In the International Breast Cancer Study Group (IBCSG), 344 patients with ≥10+ nodes received AC/EC × 4 followed by CMF × 3, or a more dose-intense arm of three cycles of EC at supraconventional, but not myeloablative, doses every 3 weeks with AHPCS [32]. At the current follow-up of 6 years, the EFS rates were 52 and 43% for the dose-intense and the standard arms, respectively ($p = 0.07$), with OS rates of 70% versus 61% ($p = 0.1$).

In the PÉGASE 01 trial, Roché et al randomized 314 patients with >7+ nodes to receive SDC followed by high-dose cyclophosphamide/mitoxantrone/melphalan or observation [33]. At a short median follow-up of 33 months, there were significant differences in EFS (71% vs. 55%, $p = 0.002$), without an OS advantage (84% vs. 85%, $p = 0.3$).

Zander et al. from the German Autologous Bone Marrow Transplant Group (GABG) randomized 307 patients with ≥10+ nodes to receive EC × 4 followed by HDC with cyclophosphamide/thioTEPA/mitoxantrone, or CMF × 3 [34]. At a median follow-up of 6 years, there were non-significant differences in favor of HDC in EFS (51% vs. 41%, $p = 0.1$) and OS (62.5% vs. 57 %, HR 0.84, $p = 0.3$).

In the study by the International Collaborative Cancer Group, 281 patients with ≥4+ nodes were randomized to receive FEC × 6 or FEC × 3 followed by HDC with STAMP-V [35]. At a median follow-up of 5.7 years, there were no differences in EFS (59% vs. 57%, $p = 0.76$) or OS (67% vs. 66%, $p = 0.4$).

A meta-analysis based on individual patient data from 15 randomized included a total of 6210 patients. After a median follow-up of 6 years, a benefit in EFS was observed after HDC (HR 0.87, $p < 0.001$), but not in OS (HR 0.94, $p = 0.13$) [36].

Prognostic factors of benefit from HDC

Retrospective studies have identified the MBC populations who are most likely to achieve long-term remissions after HDC, such as those with low tumor burden, in CR after SDC, or without liver involvement [37,38]. A prospective study of HDC with STAMP-I for MBC patients early in the course of their disease with low tumor burden (oligometastatic) was conducted at the University of Colorado [39]. At a median post-transplant follow-up of 5 years, the EFS and OS rates of 60 patients were 52 and 62%, respectively, with median EFS and OS times of 4.3 and 6.7 years, respectively (Figure 61.3a). HER2-negative status and a single metastatic site were independent favorable predictors of outcome (Figure 61.3b) [40].

Likewise, retrospective analyses have identified prognostic factors for HDC for HRPBC, including hormone receptor status, tumor size, axillary nodal status (particularly when determined by the nodal ratio between number of positive nodes and number of sampled nodes) [41,42]. HER2 status (Figure 61.4a) [43], epidermal growth factor receptor (EGFR) overexpression (Figure 61.4b) (in particular when co-overexpressed with HER2, Figure 61.4c) [44], or tumor angiogenesis (Figure 61.4d) [45].

Conclusions

Twenty-five years after its first trial for MBC, the use of HDC for breast cancer has almost ceased, with no active trials currently registered in the United States. Randomized trials in the MBC and HRPBC settings have largely failed to show OS benefits. While many of those trials were underpowered to detect realistic survival differences, their meta-analyses did not show a global OS

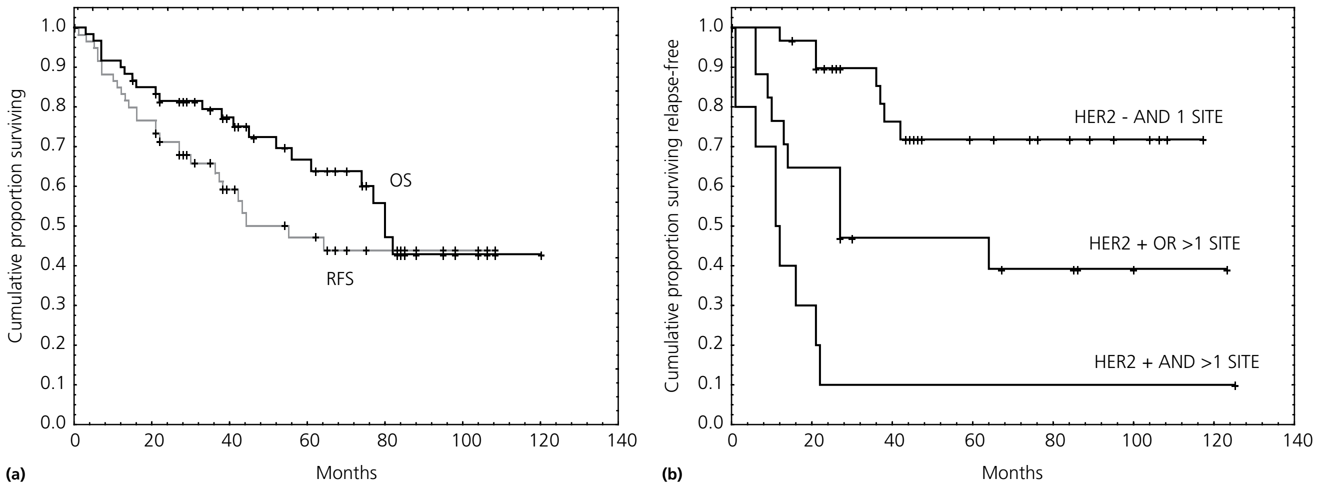

Figure 61.3 HDC for oligometastatic disease. (a) Relapse-free survival (RFS) and overall survival (OS) results of a prospective trial of STAMP-I; (b) RFS curves in this trial according to HER2 and number of metastatic sites.

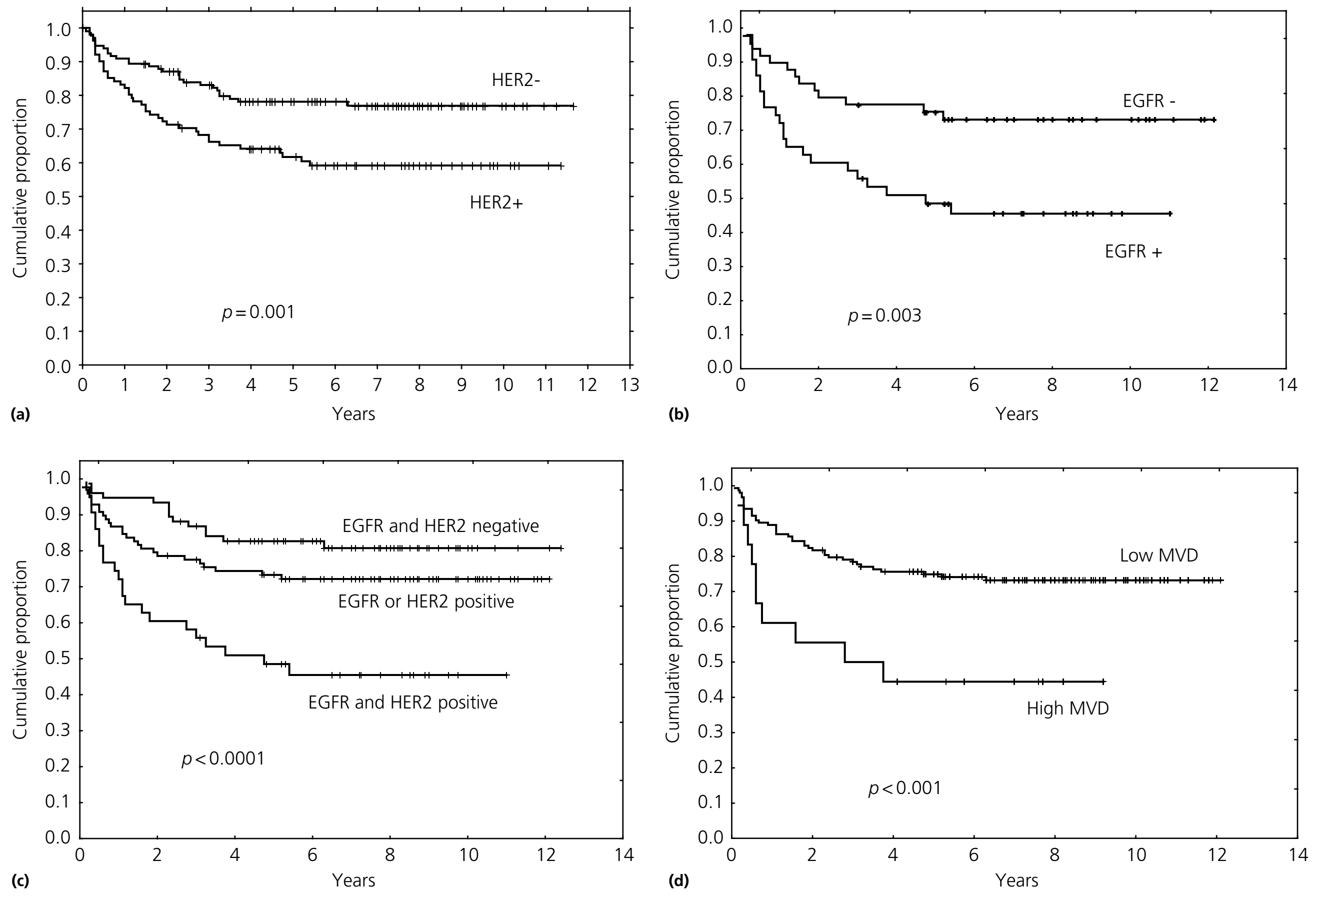

Figure 61.4 Effect of biologic prognostic factors on EFS of patients with HRPBC after HDC. (a) Effect of HER2 overexpression; (b) effect of EGFR expression; (c) combined effect of HER2 and EGFR expression; (d) effect of intratumor microvessel density (MVD).

benefit in either setting [17,36]. Those overviews, however, did detect a statistically significant 13% decrease of risk of relapse in HRPBC and a 24% decrease of risk of progression in MBC. In our view, the data do not justify the abandonment of the transplant approach to breast cancer, given the persistent need for curative treatment strategies for its advanced stages. Clearly, a fraction of patients may benefit from a high-dose approach, such as those with oligometastatic disease. In addition, and independent of whether the superior tumor debulking capacity of HDC translates into improved outcomes, post-transplant minimal residual disease would still provide an optimal scenario for application of novel therapies. In contrast to an all too common opinion, HDC and novel therapeutics targeting signal-transduction pathways are not mutually exclusive. In solid tumors, available data suggest that these promising new agents may help improve outcome when combined with chemotherapy but are unlikely to have a substantial impact alone. The anti-HER2 monoclonal antibody trastuzumab or other biological agents can be easily administered after transplant, or integrated into the high-dose regimen exploiting their synergy [46].

Personalized medicine has re-emphasized the importance of evaluating small patient populations who achieve uncommon benefit following a novel treatment [47]. For example, many trials of HDC for MBC demonstrated that 10–15% patients with advanced disease experienced EFS of more than 5-years (Table 61.3). If a sizable fraction of these patients continue in remission 15 years later, this observation may suggest the re-examination of the "incurability" of metastatic breast cancer for selected patients. These types of long-term follow-up should be reported. It would be of interest if personalized medicine concepts induce a re-examination of the importance of the "tail" of Kaplan–Meier curves using novel statistical tools [48], which might reflect a subset of cured patients.

Table 61.3 Overall results from major phase II trials of HDC with ASCT for breast cancer and germ-cell tumors

Tumor	Setting	Long-term EFS (%)	Ref.
Breast	4–9 nodes	60–70	[41]
	10+ nodes	55–65	[19,20,41,42]
	Inflammatory carcinoma	55–65	[41]
	Metastatic chemosensitive disease	10–20	[38]
	Oligometastatic disease	55	[40]
	Refractory or high-burden relapse	<5	
NSGCT	Refractory or ≥2nd relapse	15	[53–55]
	1st relapse	50	[56–67]
	First-line high-risk disease	50–70	[84–86]

NSGCT, non-seminomatous germ-cell tumor.

Germ-cell tumors

Germ-cell tumors (GCTs) represent the most common malignancy in young men between the ages of 15 and 35 years. Since the advent of modern cisplatin-based chemotherapy, cure rates for metastatic disease have reached 70–80%. The standard first-line regimen of bleomycin/etoposide/cisplatin (BEP) yields long-term EFS rates of 90% in advanced-disease good-risk patients, as defined by the International Germ Cell Consensus Classification, which decreases to 80% for intermediate-risk GCT and 50% for poor-risk patients (Table 61.4) [49]. Standard salvage regimens, based on ifosfamide and cisplatin, plus either vinblastine (VeIP) [50], etoposide (VIP) [51], or paclitaxel (TIP) [52], result in CR rates of 50–60% and long-term EFS of 20–30% of patients in first relapse. Patients in second relapse are largely incurable with standard treatment.

HDC for refractory/relapsed NSGCT

The use of tandem high-dose cycles of carboplatin/etoposide (CE) with autologous stem-cell transplantation (ASCT) as salvage therapy was pioneered by Nichols and colleagues at Indiana University in the 1980s. In sequential studies, this treatment resulted in long-term EFS rates of 15% for patients in second relapse [53–55] and 38% for those transplanted in first relapse [56,57]. The introduction of PBPCs and improvement of supportive measures allowed the re-escalation of the dose of these drugs and improvement of results [58]. Einhorn et al. subsequently reported 68% EFS at a median follow-up of 48 months in a more recent report from the Indiana group in 184 patients (135 transplanted in second-line therapy and 49 in third-line or later therapy) who received tandem cycles of carboplatin (2100mg/m^2) and etoposide (2250mg/m^2) [59]. The EFS rates in patients transplanted in first or in second or later relapse were 70 and 45%, respectively. The outcome was similar in patients with seminoma and non-seminoma histologies (74% vs. 60%). These excellent results reflect, in part, patient selection, with no patients with late relapses or primary mediastinal tumors included, and around one-third of the patients presenting features predictive of good outcomes with SDC alone.

Several groups have tested the addition of a third drug to the CE backbone. Motzer et al. treated 58 cisplatin-refractory patients with two cycles of carboplatin/etoposide/cyclophosphamide (CEC), with a 40% CR rate and 21% EFS rate at a median follow-up of 28 months [60].

Table 61.4 Risk stratification of newly diagnosed patients (International Germ Cell Consensus Classification)

	Non-seminoma		Seminoma	
Low risk	• Testis or retroperitoneal primary *and* • No non-pulmonary visceral metastases *and* • Good markers (AFP < 1000ng/mL *and* B-HCG < 5000IU/L *and* LDH < 1.5ULN)	• 56% patients • 90% EFS at 5 years	Any primary site *and* • No non-pulmonary visceral metastases *and* • Normal AFP, any B-HCG, any LDH	• 90% patients • 80% EFS at 5 years
Intermediate risk	Testis or retroperitoneal primary *and* • No non-pulmonary visceral metastases *and* • Intermediate markers (AFP 1,000–10,000ng/mL *or* B-HCG 5,000–50,000IU/L *or* LDH 1.5–10ULN)	• 28% patients • 80% EFS at 5 years	• Testis or retroperitoneal primary *and* • Non-pulmonary visceral metastases *and* • Normal AFP, any B-HCG, any LDH	• 10% patients • 67% EFS at 5 years
Poor risk	• Mediastinal primary, *or* • Non-pulmonary visceral metastases *or* • Poor markers (AFP >10,000ng/mL *or* B-HCG >50,000IU/L *or* LDH >10ULN)	• 56% patients • 50% EFS at 5 years		

ULN, upper limit of normal.

Siegert et al. treated 74 patients with recurrent disease with two SDC cycles followed by one cycle of HDC with ifosfamide/carboplatin/etoposide (ICE), with 50% 2-year EFS rates among patients with sensitive tumors, but only 4% EFS in those with refractory disease [61]. Margolin et al. reported a 45% EFS rate after tandem cycles of high-dose ICE in 20 patients with relapsed, cisplatin-sensitive tumors [62]. The same group subsequently treated 31 relapsed patients with sequential cycles of HDC with paclitaxel (425mg/m^2 over 24 hours)/carboplatin/etoposide (cycle 1) and ICE (cycle 2) [63]. At a median follow-up of 5.5 years, 12 patients (39%) remained free of disease. Rick et al. treated 80 patients, most with cisplatin-sensitive disease, with 3–4 cycles of SDC followed by one cycle of high-dose carboplatin/etoposide/thioTEPA [64]. At a median follow-up of 3 years, the EFS rate was 26%. Overall, high-dose triplets achieve 40–50% EFS rates in patients with cisplatin-sensitive tumors, and 4–20% in those with refractory disease [65,66].

Feldman et al. tested the use of three cycles of HDC, and reported encouraging results in 107 patients with relapsed disease and unfavorable prognostic features treated with two biweekly cycles of paclitaxel/ifosfamide followed by high-dose CE × 3 (TICE), with 47% DFS at 5 years [67].

A novel strategy to improve results attempts to modulate the effect of HDC with biologic agents. GCTs are highly vascularized and express vascular endothelial growth factor (VEGF) prominently. The expression of this angiogenic factor correlates closely with microvessel density within metastatic GCT lesions, which has been associated with prognosis [68,69]. Use of a single dose of the anti-VEGF monoclonal antibody bevacizumab before chemotherapy decreases the tumor interstitial fluid pressure and enhances access of the cytotoxic drugs into the solid tumor lesions [70]. Attempting to exploit their synergy, investigators at the M.D. Anderson Cancer Center are conducting a phase II trial of sequential cycles of bevacizumab–HDC in highly refractory or multiply relapsed patients. A preliminary analysis of their phase II trial of bevacizumab–gemcitabine/docetaxel/melphalan/carboplatin followed by bevacizumab–ICE showed very encouraging early results, with a 2-year EFS of 60% in a population with very poor prognosis [71].

Can we predict the outcome of patients with relapsed GCT receiving HDC?

Beyer et al. analyzed 283 relapsed/refractory patients treated with CE [72]. They identified the following independent adverse predictors: refractoriness to cisplatin (progression within 4 weeks after treatment with cisplatin), absolute refractoriness to cisplatin (no response to initial platinum chemotherapy), primary mediastinal tumor, and high tumor markers [human chorion gonadotropin (HCG) >1000U/L] at the time of HDC. A prognostic score based on these variables was developed (Table 61.5). The resulting good-, intermediate-, and poor-risk groups presented 2-year EFS of 51, 27,

Table 61.5 Prognostic models for HDC for NSGCT

Model		Factor		Points	2-year EFS (%)
Beyer	Variables	Progressive disease before HDC		1	
		Mediastinal primary tumor		1

		Very high risk		>4	22

and 5%, respectively. This model was externally validated in a group of 45 patients with cisplatin-refractory relapsed disease, treated with HDC using ICE × 2, where the subsets with good, intermediate and poor risk had 62, 13, and 0% EFS rates, respectively, at a median follow-up of 32 months [73]. The Beyer model was based on patients treated between 1984 and 1993, and most of them had received a single course of HDC. Of these patients, 91% had failed at least one prior salvage regimen.

Einhorn et al. developed a different prognostic model based on their experience in 184 patients treated at Indiana University with tandem CE [59]. Patients with primary mediastinal tumors were not included for this analysis owing to their earlier findings that none of the patients that the authors had treated were alive and free of disease at 2 years [74]. Three independent adverse prognostic factor were identified: an International Germ Cell Cancer Collaborative Group (IGCCCG) poor-risk classification at initial diagnosis, cisplatin-refractory disease [defined as progressive disease (PD) within 4 weeks of most recent cisplatin-based chemotherapy] and administration of HDC as third-line or later treatment. Patients in the low-, intermediate-, and high-risk categories had EFS rates of approximately 80, 60, and 40%, respectively.

The International Prognostic Factor Study Group (IPFSG) analyzed 1594 patients treated after 1990 with HDC (n = 821) or SDC (n = 773) as first salvage therapy [75]. Among patients receiving HDC, half received a single cycle and the other half received tandem cycles. Seven factors were found to be independent predictors of outcome, after either SDC or HDC: primary tumor site (mediastinal vs. retroperitoneal vs. gonadal), response to first-line therapy, length of prior progression-free interval, α-fetoprotein (AFP) at salvage, β-HCG at salvage, and presence of non-pulmonary visceral metastases. A composite score based on these factors assigns patients to a very low (only seminoma), low, intermediate, high or very high risk categories. Within each prognostic category, PFS at 2 years was significantly superior after HDC compared with SDC, which translated into improved OS (Table 61.6). The strengths of this international analysis are its very large sample size and the requirements of a well-documented unequivocal progression or relapse, and also of prior use of modern first-line and salvage treatments. It is applicable to patients receiving either SDC or HDC at the time of first recurrence, a setting in which it seems more applicable than the other two models. In both the IPFSG and Beyer models, HDC was administered in either one (50 and 91% of the patients, respectively) or tandem (50 and 9%, respectively) cycles. In contrast, all patients in the Indiana model received tandem cycles.

Table 61.6 EFS and OS rates in patients treated with HDC or SDC (International Prognostic Factors Study Group)

Patients	Treatment	2-yr EFS (%)	*p*	5-yr OS (%)	*p*
All patients	SDC	28	<0.001	41	<0.001
(n = 1594)	HDC	50		53	
Very low risk	SDC	58	<0.001	64	<0.01
(n = 76)	HDC	92		89	
Low risk	SDC	40	<0.001	66	0.98
(n = 257)	HDC	64		64	
Intermediate risk	SDC	32	<0.001	45	<0.001
(n = 646)	HDC	53		58	
High risk	SDC	17	<0.001	23	<0.005
(n = 351)	HDC	33		35	
Very high risk	SDC	2	<0.001	3	<0.001
(n = 105)	HDC	22		27	

Both the Beyer and the Indiana models are applicable to patients in second or later relapses. Whereas the Indiana model reflects better the common US practice of using tandem HDC cycles, the Beyer score seems more capable of detecting a very poor prognosis subset of patients, for whom novel approaches are clearly needed.

Randomized trials of HDC in the salvage setting

Retrospective matched-pair comparisons of HDC with SDC for patients in first relapse have suggested a large benefit from transplant [76,77]. Pico et al. at the European Group for Blood and Marrow Transplantation (EBMT) conducted the only randomized trial to date comparing HDC with SDC in relapsed patients. They randomized 280 relapsed patients to receive three cycles of SDC followed by one more cycle (SDC arm) or a single course of high-dose CEC with ASCT (HDC arm) [78]. At a median follow-up of 45 months, no differences in EFS (35% vs. 42%, p = 0.16) or OS (53% in both arms) were apparent. This trial has been criticized because of a 30% drop-out rate in the HDC arm, the higher than expected treatment-related mortality in both study arms (3 and 7%, respectively), and the use of a single rather than sequential cycles of HDC.

Lorch et al. randomized 216 patients with relapsed or refractory disease to receive one cycle of high-dose CE or two sequential cycles of those drugs at slightly lower doses, requiring AHPCS in both arms [79]. Accrual to this study stopped after an excessive 14% TRM was detected in the single cycle arm. Ata median follow-up of 3 years, the differences in favor of the sequential HDC arm in EFS (40% vs. 37%) and OS rates (80% vs. 61%) did not reach statistical significance.

In summary, there is no consensus yet as to whether HDC should be considered for all patients at the time of first relapse. Results of tandem cycles of HDC as salvage treatment appear superior to those expected with SDC, which have prompted many to consider HDC the standard salvage treatment [80], despite the absence of evidence of benefit from randomized studies. It is possible that more than one cycle of HDC is necessary to achieve a favorable outcome, and that a single cycle, as administered in the European randomized study, may not be sufficient to improve results. Of note, in the IPFSG analysis, the 2-year DFS rates for patients receiving sequential HDC cycles appeared superior to those receiving a single high-dose cycle (55% vs. 44%, $p < 0.001$). An international randomized phase III trial comparing TICE with three cycles of HDC with to SDC with four cycles of TIP will soon address this important question [81].

Other areas of uncertainty

It is unclear whether patients with relapsed primary mediastinal GCT can achieve benefit from HDC. Patients with relapsed primary mediastinal germ-cell tumors (PMGCTs) have typically been reported to present very poor outcomes after HDC, which has led some investigators to abandon this strategy for these patients [82]. In contrast, others have reported long-term CRs within this population in their HDC studies [67,79].

Late relapses, defined as recurrence 2 years or longer following a CR to cisplatin-based first-line therapy, are a disconcerting syndrome characterized for its poor response to chemotherapy. While surgery is the preferred approach [83]. it remains unclear whether patients with unresectable late relapses might benefit from HDC as some data have suggested [79].

First-line HDC for poor-risk NSGCT

Motzer et al. at the Memorial Sloan Kettering Cancer Center developed a strategy of switching to HDC those patients showing a reduced clearance and prolonged half-life of tumor markers during

SDC [84]. This approach yielded a CR rate of 57%, EFS of 50% at a median follow-up of 30 months, and significantly longer OS than for historical controls from the same institution.

Schmoll et al. reported long-term results of HDC in 221 patients with advanced poor-prognosis disease, who received one cycle of SDC followed by three cycles of high-dose VIP (high-dose etoposide/ifosfamide + standard-dose cisplatin) [85]. At a median follow-up of 4 years, the EFS rate was 69%. Non-randomized matched-pair comparisons of patients enrolled in this trial with others enrolled in trials of SDC suggested superiority of HDC [86].

The role of HDC in first-line therapy has been evaluated in three randomized studies. A European randomized trial conducted in the 1980s failed to show a therapeutic benefit for HDC in 115 untreated poor-risk patients, who were randomized to receive 3–4 cycles of SDC or two cycles followed by one cycle of a stem-cell-supported high-dose cisplatin-containing regimen [87]. Patients randomized to the transplant arm received less total cisplatin than those on the standard-dose arm, and also an HDC regimen that can be considered substandard by present criteria. It is therefore felt that this study did not appropriately address the role of first-line HDC in poor-risk GCT.

A European study compared SDC with BEP × four cycles with one cycle of VIP followed by three cycles of high-dose VIP with ASCT in patients with poor-risk features by the IGCCCG criteria [88]. This study closed prematurely after slowly enrolling only 137 of the 222 planned patients. At its first analysis with a median follow-up of 4.4 years, the 2-year EFS (45% vs. 58%, $p = 0.06$) and 2-year OS (66% vs. 73%, $p > 0.05$) differences did not reach statistical significance.

In a US Intergroup trial, Motzer et al. randomized 219 patients with newly diagnosed disease with intermediate- or poor-risk features according to the IGCCCG criteria to receive four cycles of BEP or two cycles of BEP followed by two cycles of HDC with CEC [89]. The 1-year durable CR rates did not differ significantly between the transplant and control arms (48 vs. 52%, $p = 0.5$). There were no significant differences in EFS ($p = 0.4$) or OS ($p = 0.9$). A planned subset analysis according to early tumor marker clearance suggested a significant benefit of HDC among those patients experiencing a slow marker decline (1-year EFS 61% vs. 34%, $p = 0.03$), in contrast with similar outcomes in both arms in the group of patients with a satisfactory marker drop ($p = 0.5$). Given the small size of this subset analysis, these provocative observations are not robust enough to allow firm conclusions to be drawn.

In summary, the available data from randomized trials indicate that there is currently no standard role for HDC in first-line treatment of GCT.

Special considerations

Surgical management after HDC

A retrospective review of the German experience identified 216 patients treated in three consecutive HDC trials between 1989 and 1999 [90]. Partial remissions with negative or positive tumor markers after high-dose chemotherapy were achieved in 128 patients (59%). Of these patients, 57 (45%) proceeded to residual tumor resection; the remaining 71 (55%) could not be operated on because of PD, unresectability of the tumor masses, poor performance status, or patient refusal. With a median follow-up of 87 months, 37/57 patients (65%) were alive, 34 of whom (59%) remained continuously disease free. Viable cancer was documented in the resected specimen of 26 (46%) of the 57 patients. The 5-year EFS rates in patients with and without viable cancer were 42 and 84%, respectively ($p < 0.01$). Of note, all patients in this series had been treated with a single cycle of high-dose chemotherapy, which likely influenced the incidence of viable cancer in resected specimens. This report indicates that post-chemotherapy resection can contribute significantly to overall treatment outcome, and that residual tumor resection should be considered in patients in partial remission after HDC.

Management of relapse post-HDC

A retrospective review of the Indiana University experience identified 101 patients who relapsed after HDC after a median interval of 10 months. Forty-seven of them subsequently received salvage SDC, with an overall RR of 18.2% and a CR rate of 5%. Seven patients underwent surgery alone, with only one long-term survivor [91].

Two prospective trials have studied salvage SDC for relapse after HDC. In a phase II trial at Indiana University, 32 patients with PD after CE × 2 received paclitaxel/gemcitabine [92]. Patients who had received either agent prior to HDC were ineligible. A response was achieved by 10 patients (31%), including six CRs and four PRs (of 2–6 months' duration). Four patients in CR (12.5%) were continuously disease free without any additional treatment at 20–57 months from paclitaxel/gemcitabine. One additional CR patient was rendered disease free after two subsequent resections of tumor. A German study enrolled 32 patients with relapse after HDC and nine patients with cisplatin-refractory disease who were rescued with gemcitabine/oxaliplatin/paclitaxel [93]. Two patients (6%) achieved a CR, 34% achieved a marker-negative PR, and 12% achieved marker-positive PR, with an overall RR of 51%.

Therefore, although outcomes have been largely unfavorable for patients who relapse after HDC, these trials point to some possibility of successful chemotherapeutic salvage even in heavily pretreated and cisplatin-refractory patients.

Conclusion

There is currently no standard role for HDC in first-line treatment of GCT. Definition of its role as part of first-line salvage awaits completion and analysis of the upcoming international randomized trial. HDC is widely considered a valid treatment option for patients with refractory disease or in second relapse or later (Table 61.3).

CHAPTER 62

Hematopoietic Cell Transplantation for Renal Cell Carcinoma and Other Solid Tumors

Richard W. Childs and Ramaprasad Srinivasan
National Institutes of Health, Bethesda, MD, USA

Introduction

Our perception of the mechanisms through which malignant cells are eradicated following allogeneic hematopoietic cell transplantation (HCT) has evolved substantially over the past four decades. No longer merely thought of as a means of rescuing hematopoietic function following high-dose conditioning, allogeneic transplantation is now known to be a powerful type of immunotherapy capable of curing patients with otherwise fatal malignant diseases. This conceptual evolution has translated into a diversification of the indications for allogeneic HCT and led to the development of reduced-intensity transplant approaches whose beneficial antineoplastic effects can be attributed largely to the transplanted donor immune system. Over the past 10–15 years, several groups have sought to determine whether non-hematologic malignancies might likewise be susceptible to allogeneic immune attack. In this chapter, we highlight recent work that has improved our awareness and understanding of the graft-versus-tumor (GVT) effect, and discuss the current results of its application as an investigational therapeutic modality in the treatment of metastatic solid tumors.

Allogeneic transplantation as immunotherapy: the GVT effect

Acute leukemias have traditionally been viewed as “chemosensitive” malignancies. The inability to “cure” the majority of adults with leukemia following conventional chemotherapeutic regimens was attributed at least in part to a failure to deliver the sufficiently high doses of antineoplastic agents required to eradicate all malignant cells. Dose-limiting toxicities, including prolonged delays in lymphohematopoietic recovery, significantly hindered efforts to intensify such regimens. Pioneering work by E.D. Thomas and others led to the development of allogeneic HCT as a means of accelerated recovery of lymphohematopoietic function following the administration of high-dose chemotherapy [1,2].

For the next two decades, allogeneic HCT became increasingly used as a therapeutic option to treat patients with a variety of different treatment-resistant hematologic malignancies. Initially, the curative potential of the procedure was ascribed solely to the cytotoxic effects of the conditioning regimen, be it chemotherapy alone or in conjunction with total body radiation. It was not until years following its inception that investigators first documented the very important and powerful immune mechanisms that contributed to the curative potential of the approach in humans.

Throughout the 1980s, several landmark observations provided insights into this phenomenon known as the “graft-versus-tumor” effect. First, in an analysis of over 200 patients with hematologic malignancies undergoing human leukocyte antigen (HLA)-matched HCT from a sibling donor, investigators noted that patients who experienced moderate-to-severe acute graft-versus-host disease (GVHD) or chronic GVHD had a significantly lower incidence of leukemic relapse compared with patients with little or no GVHD [3]. Similar benefits in disease-free survival were observed in recipients of HLA-identical (non-twin) sibling donor allografts compared with those receiving syngeneic allografts [4], and also in recipients of T-cell-replete grafts versus those receiving T-cell-depleted transplants [4–7]. These observations suggested a very important role for donor T cells in mediating this effect, and also implicated the targets of GVT as falling outside the realm of antigens encoded by the major histocompatibility complex (MHC). Definitive evidence that GVT effects were clinically meaningful came from studies in patients with chronic myelogenous leukemia who relapsed post-transplant and were subsequently induced back into remission following a donor lymphocyte infusion (DLI) [6].

Over the last two decades, numerous investigators have successfully exploited GVT effects against a variety of malignancies of hematopoietic origin, including both acute and chronic leukemias, lymphomas, multiple myeloma, and Epstein–Barr virus (EBV)-related lymphoproliferative disorder [8–16]. The ability of GVT to induce remission varies among these malignancies, with the critical determining factors dictating susceptibility to GVT being not entirely understood.

The immune system and solid tumors

Tumors such as metastatic melanoma and renal cell carcinoma (RCC), with their ability to undergo occasional spontaneous regression or maintain prolonged periods of stable disease, have long fascinated investigators and led to the concept that the immune system might play a role in the regulation or control of malignant cells. Indeed, the first spontaneous regression of metastatic RCC after nephrectomy was described in 1928 and was attributed to an antibody-mediated immune response [17]. The propensity of nude (athymic) mice to develop lymphoreticular tumors, and the increased incidence of malignancies in patients with congenital or acquired immunodeficiency states, lent further credence to the

notion that the immune system might play a role in the control of cancer [18,19]. The development of immune-based therapeutic strategies against metastatic solid tumors was a logical consequence of these observations.

At the National Cancer Institute (NCI), pilot immunotherapy trials in patients with advanced solid tumors – particularly metastatic RCC and metastatic melanoma – were conducted in the early 1980s by Rosenberg and colleagues [20]. The earliest trials were intended to non-specifically stimulate innate immune responses against tumors using cytokines such as interleukin-2 (IL-2). In their preliminary experience using IL-2 in patients with either metastatic RCC or melanoma, overall response rates of 20% (RCC) and 17% (melanoma) were observed. Importantly, some patients achieved complete and durable remission of disease, providing valuable proof of concept of the therapeutic potential of immune-based therapeutic strategies. Subsequent studies conducted at the NCI and also by the Cytokine Working Group employed adoptive transfer of lymphokine-activated killer cells or ex vivo-expanded tumor-infiltrating lymphocytes in conjunction with IL-2. Although response rates in early trials approached 35%, further evaluation suggested that tumor-infiltrating lymphocyte therapy provided little additional therapeutic benefit over cytokine treatment alone [21–27]. More recently, investigators have evaluated the use of immunosuppressive chemotherapy prior to infusion of IL-2 and autologous tumor infiltrating lymphocytes in an attempt to promote selective in vivo expansion of cytotoxic T-lymphocytes (CTLs). This approach has met with some success in patients with metastatic melanoma, but is yet to gain widespread acceptance in clinical practice [28,29]. The low response rates and significant morbidity that were frequently associated with such therapy (particularly high-dose IL-2) provided the impetus for the exploration and development of immune strategies that would selectively target the tumor.

The foundation for tumor-specific cellular immunotherapy was laid following the identification of a number of different tumor-associated antigens (TAAs) in melanoma and other solid tumors [30–32]. Several clinical trials have evaluated the safety and efficacy of cancer vaccines designed to enhance immune responses to TAAs. Although immune correlative studies have shown that some vaccines significantly expand TAA-reactive T-cell populations in vivo, early clinical results from such trials have been modest.

Several factors likely contribute to the poor clinical efficacy of conventional vaccine strategies designed to enhance "self" immunity against TAAs. To date, most trials have used an MHC class I-restricted peptide-based approach. As a consequence, resultant immune responses are limited to a single antigenic epitope devoid of a critical CD4$^+$ helper T-cell component [33]. Furthermore, such vaccine strategies may favor the selection of tumor cells lacking the targeted antigen, a phenomenon described as "antigen escape." Modifying this approach by simultaneously immunizing with multiple tumor antigens that are both MHC class I and II restricted, or by using the tumor itself as a vaccine (tumor lysates, tumor apoptotic bodies, etc.), may partly overcome this limitation [34]. It has also been suggested that tumors may evade CTLs by downregulating expression of accessory molecules required by CTLs to mediate lysis or by engaging inhibitory cell surface receptors such as CTLA-4 and PD-1 expressed on T-lymphocytes. Indeed, inhibitors of both CTLA-4 and PD-1 are being actively explored in patients with solid tumors as a means of circumventing tumor-mediated immune suppression and promoting innate antitumor immunity. Ipilimumab, an antibody against human CTLA-4, has been shown in randomized phase III studies to prolong survival in patients with metastatic melanoma, while several antagonists of the PD-1 pathway are currently being evaluated in early-phase clinical trials with promising activity in several solid tumors including melanoma and RCC [35].

Perhaps one of the greatest limitations of conventional immunotherapy is that the host immune system that it attempts to enhance has intrinsic functional compromise. A number of lines of evidence support this concept. First, the host immune system is often rendered incompetent by prior chemotherapy and/or by tumor-related factors. Second, longstanding immune tolerance to tumor antigens, including TAAs targeted by conventional cancer vaccines, may exist. Theoretically, these limitations could be circumvented by allogeneic HCT, a procedure that culminates in complete host immune replacement. Perhaps more importantly, unlike innate host immunity, an allogeneic immune system would have the capacity to mount immune responses to polymorphic variants of tumor-specific or broadly expressed minor histocompatibility antigens (mHAs) [36–38].

Solid tumors as a GVT target

Animal models exploring graft-versus-solid tumor effects

The notion that immune responses following allogeneic HCT can be directed against solid tumors was first tested in animal models in the early 1980s. Using a mouse model, Moscovitch and Slavin showed that the high incidence of spontaneous lymphosarcomas in NZ B/W hybrids could be significantly diminished by the transplantation of allogeneic hematopoietic stem cells from BALB/c mice [39]. Subsequently, this group demonstrated the ability of minor and major histocompatibility antigen-mismatched transplants to protect mice from developing metastatic disease following mouse mammary adenocarcinoma (4T1) tumor challenge [40,41]. These experiments showed that alloimmune responses against mHAs that were expressed on tumors could be generated following hematopoietic stem cell transplantation.

Early clinical data suggesting GVT effects against solid tumors in humans

Compelling clinical evidence supporting the therapeutic utility of the GVT effect in hematologic malignancies prompted investigators to explore allogeneic HCT as a therapeutic tool against metastatic solid tumors in the late 1990s. The first report suggesting a possible GVT effect against a tumor of epithelial origin noted the incidental regression of a metastatic breast adenocarcinoma lesion following allogeneic HCT for relapsed acute myeloid leukemia [42]. Subsequently, Eibl et al. reported tumor regression coincident with acute GVHD in a patient with chemotherapy-resistant metastatic breast cancer following a high-dose transplant from an HLA-identical sibling [43]. The ability to expand mHA-specific CTLs (obtained from the patient at the time of clinical response) that lysed breast cancer cell lines in vitro lent credence to the argument that the tumor regression was at least in part mediated by alloimmune T-cell-mediated mechanisms. Investigators at the M.D. Anderson Cancer Center reported their experience in 10 patients with metastatic breast cancer who received an allogeneic HCT from an HLA-matched sibling following high-dose conditioning [44]. One complete response (CR) and five partial responses (PRs) were noted. GVT effects were implicated in at least two patients whose tumor regression was temporally associated with the onset of acute GVHD and withdrawal of immunosuppression. Delayed regression of metastatic lesions following high-dose allogeneic HCT in a woman with ovarian cancer offered further evidence that some tumors of epithelial origin were indeed susceptible to GVT effects [45].

Use of reduced-intensity conditioning in allogeneic transplantation for solid tumors

By the late 1990s, there was sufficient interest in studying GVT effects against solid tumors based on available preclinical and clinical data. The major factor limiting the initiation of pilot trials was the significant morbidity and mortality associated with conventional allogeneic HCT. Dose-intensive conditioning used to provide both tumor cytoreduction and promote donor engraftment contributed in part to the morbidity and mortality associated with HCT. Subsequently, it was recognized that reducing the intensity of the preparative regimen might translate to a reduction in the risk of early, conditioning-related morbidity and mortality.

In the late 1990s, transplant regimens using reduced-intensity conditioning (RIC) were designed by a number of investigators, and were evaluated for their engraftment potential and toxicity profile [46–50]. Two major factors impacted on the design and development of these dose-reduced conditioning regimens. First was the recognition that GVT effects alone might be sufficient to eradicate some hematologic malignancies in the absence of dose-intensive therapy. Second was the realization that the primary role of the conditioning regimen might be limited to preparing the recipient for engraftment by inducing adequate host immunosuppression. Thus, RIC regimens were designed using agents that would induce adequate immunosuppression to facilitate donor immune engraftment while maintaining a low toxicity profile. Such "low-intensity" regimens were first evaluated in hematologic malignancies known to be responsive to allogeneic HCT. Pilot trials utilizing RIC HCT demonstrated that such regimens were generally well tolerated, having a decreased incidence of transplant-related morbidity and mortality, while achieving sufficient donor immune engraftment to induce sustained remissions of some hematologic malignancies [46–50].

One of the major contributions of RIC was that it allowed for the extension of allogeneic HCT to debilitated and older patients who, because of the high risk of treatment-related mortality (TRM) with conventional myeloablative conditioning, would ordinarily have been denied the benefit of a procedure with curative potential. Importantly, investigators anticipated that the overall risk of TRM would be lower with a reduced-intensity approach, a notion which emboldened them to explore for GVT effects against solid tumors.

Clinical results of reduced-intensity allogeneic HCT transplantation in solid tumors

RCC: the National Institutes of Health experience

The current worldwide clinical experience of RIC HCT for solid tumors is limited, and the approach continues to be experimental. Because there was no convincing evidence to support the existence of a GVT effect in solid tumors, and given the potential for considerable morbidity with HCT, early pilot trials were restricted primarily to terminally ill patients with advanced treatment-refractory metastatic disease. At present, RCC remains the solid tumor in which allogeneic antitumor responses have been best characterized.

Several factors provided an incentive to study the susceptibility of this malignancy to a GVT effect. First, metastatic RCC is a uniformly fatal cancer in which the majority of patients succumb to their disease within 2–3 years of diagnosis. Second, despite the recent introduction of targeted agents against the vascular endothelial growth factor (VEGF), therapeutic options are extremely limited, with conventional chemotherapy and radiotherapy being largely ineffective [51]; furthermore, these targeted agents are seldom, if ever, curative, with the majority of patients experiencing disease progression within 1 year of treatment initiation. Third, RCC is considered an "immunoresponsive" tumor based on its susceptibility to cytokine therapy [20,52,53], reports of occasional spontaneous regression [17,54], and the existence of tumor-infiltrating T-lymphocytes in regressing metastatic lesions [22,26]. These considerations led to the development of a clinical protocol at the National Institutes of Health (NIH) that sought to test the safety and efficacy of RIC HCT in patients with cytokine-refractory metastatic RCC [46,55].

The primary considerations in the design of the allogeneic HCT trial for patients with metastatic kidney cancer were the following:

1. devising a conditioning regimen that would ensure maximal host immunosuppression to favor rapid and complete donor immune engraftment with relative sparing of recipient myeloid progenitors;
2. devising a post-transplant immunosuppressive approach that would provide optimal prophylaxis for GVHD without precluding the ability to initiate a donor immune-mediated GVT effect;
3. judicious use of DLIs to overcome donor tolerance to host antigens for the promotion of a GVT effect;
4. appropriate patient selection: choosing patients with treatment-refractory metastatic disease who would be anticipated to survive at least as long as would be required for a delayed GVT effect to occur (i.e., 4–6 months).

Therefore, the presence of evaluable metastatic disease, a good performance status (Eastern Cooperative Oncology Group grade 0–1), adequate organ function, and a life expectancy of at least 3 months were prerequisites for patient enrolment.

Cyclophosphamide and fludarabine have profound immunosuppressive effects and are well tolerated when given in combination to treat patients with low-grade lymphoproliferative disorders [56,57]. Accordingly, we devised an RIC HCT approach in which patients received a conditioning regimen consisting of cyclophosphamide [60mg/kg × 2 days) and fludarabine [25mg/m^2 × 5 days), followed by infusion of an unmanipulated, granulocyte colony-stimulating factor-mobilized peripheral blood hematopoietic cell graft from a 6/6 or 5/6 HLA antigen-matched sibling donor (Figure 62.1). Lineage-specific engraftment of donor myeloid ($CD14^+$/$CD15^+$) and T cells ($CD3^+$) was quantitated from post-transplant peripheral blood lymphocyte samples using a polymerase chain reaction-based analysis of either variable number tandem repeats or short tandem repeats polymorphic between patient and donor (Figure 62.2).

Based primarily on animal data showing a decreased risk of GVHD following RIC HCT, we chose to use single-agent cyclosporine (CSP) as GVHD prophylaxis in our initial patient cohort. Much to our surprise, a high probability of grade II–IV acute GVHD (actuarial probability 56%) was observed in the first 25 patients with RCC who were treated (which was lethal in three cases). Consequently, mycophenolate mofetil (MMF) and, more recently, methotrexate, were added to CSP as GVHD prophylaxis in the second cohort of RCC patients. Gradual withdrawal of CSP/MMF was initiated on day 30 or 60 after transplantation, with the timing and rapidity of immunosuppression tapering being dictated by the rate of tumor progression, degree of donor T-lymphoid chimerism, and presence or absence of GVHD. One or more dose-escalated DLIs were administered to all patients with mixed T-cell chimerism, progressive disease, or partial remissions in the absence of acute or chronic GVHD. Since interferon (IFN) has been shown

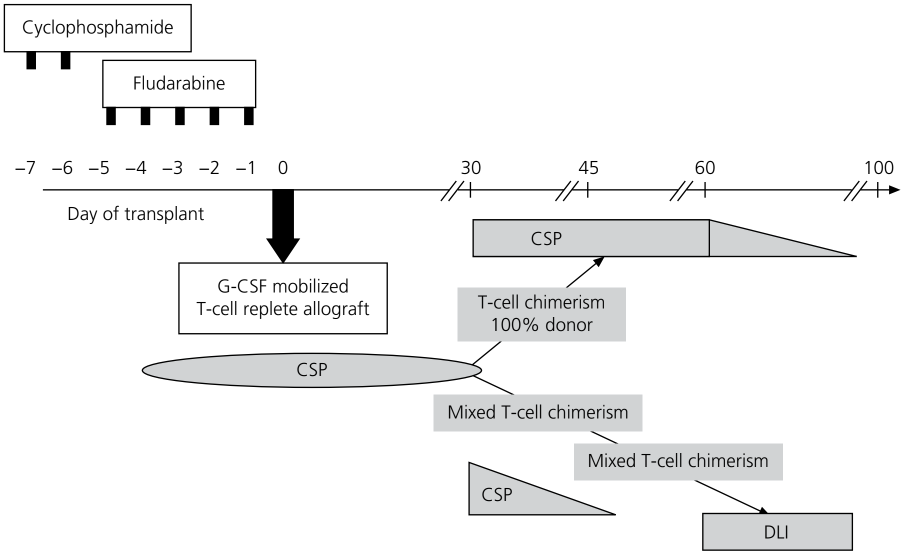

Figure 62.1 Cyclophosphamide- and fludarabine-based reduced-intensity conditioning hematopoietic cell transplantation protocol for renal cell carcinoma. CSP, cyclosporine; DLI, donor lymphocyte infusion; G-CSF, granulocyte colony-stimulating factor.

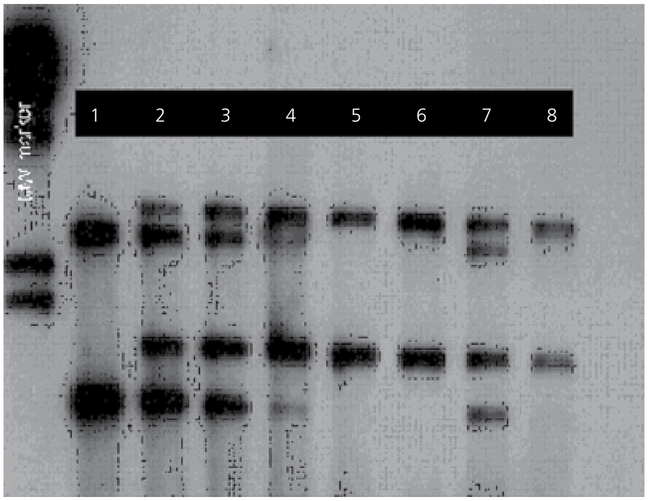

Figure 62.2 Example of polymerase chain reaction-based analysis of two different minisatellites polymorphic between patient and donor. Patient (lane 1) and donor (lane 5) lanes show two patient-specific and two donor-specific bands. Also shown are control mixtures of donor-into-patient DNA representing 30% (lane 2), 50% (lane 3), and 90% donor chimerism (lane 4), and post-transplant blood sample sorted into lineages using magnetic beads showing 100, 60, and 99% donor chimerism in $CD2^+/CD3^-$ natural killer cell (lane 6), $CD14^+/15^+$ myeloid cell (lane 7), and $CD3^+$ T-cell fractions (lane 8), respectively.

to upregulate MHC expression on RCC tumor cells in vitro (Figure 62.3), we hypothesized that using this cytokine post-transplant might make the tumor a better target for a GVT effect. Therefore, patients without GVHD who failed to respond to DLI were eligible to receive post-transplant cytokine therapy with IFN-±, either alone or in combination with IL-2.

The initial experience of RIC HCT in metastatic RCC was published in 2000 [46]. Ten of the first 19 patients treated with this transplant approach had tumor shrinkage, including three who had a CR and seven who had a PR. At present, 74 patients have undergone RIC HCT for RCC at the NIH. Of these, 73 demonstrated durable engraftment, achieving 100% donor T-cell chimerism by day 100 post-transplant. Twenty-nine of the 74 patients (39%) have had a disease response, including seven CRs and 22 PRs [58]. Five patients who were deemed to be “non-responders” had radiographic evidence for a mixed response. Disease regression was temporally associated with acute and chronic GVHD in many patients, was typically delayed in onset, and did not occur until CSP was tapered, consistent with an alloimmune-mediated GVT effect. Several patients have had a durable disease response, including the first complete responder, who remains without evidence of metastatic disease now over 14 years post-transplant (Figure 62.4). Regression of disease in multiple metastatic foci has been observed, although pulmonary responses appear to occur most frequently. On occasion, disease responses have been dramatic and have included complete resolution of large pulmonary metastases and bulky adenopathy (Figure 62.5).

Preliminary data suggest that disease response following RIC HCT is a clinically meaningful phenomenon since regression of metastatic RCC appears to be associated with a trend towards improved survival. Median survival in non-responders has been less than 6 months, in contrast to those achieving a PR, who survived a median 2.5 years post-transplant. In general, patients with metastatic kidney cancer have tolerated this conditioning regimen well. Although virtually all patients developed febrile neutropenia, we observed no sinusoidal obstructive syndrome of the liver or chemotherapy-associated mucositis. About 28% (21 of 74) of patients developed cytomegalovirus antigenemia, with only one case of cytomegalovirus disease (esophagitis) that was responsive to gancyclovir therapy. Mortality associated with transplant-related complications occurred in eight of 74 patients (11%), with either infection or acute or chronic GVHD being the major cause of TRM. Since kidney cancer frequently metastasizes to the lungs, some patients with RCC may be at high risk for the development of postobstructive pneumonia following transplantation. Such a complication occurring in the profoundly immunocompromised can lead to disastrous infectious sequelae, as was observed in two of our RCC patients who died from bacterial sepsis related to obstructive bronchial pneumonia. Most deaths related to acute GVHD occurred

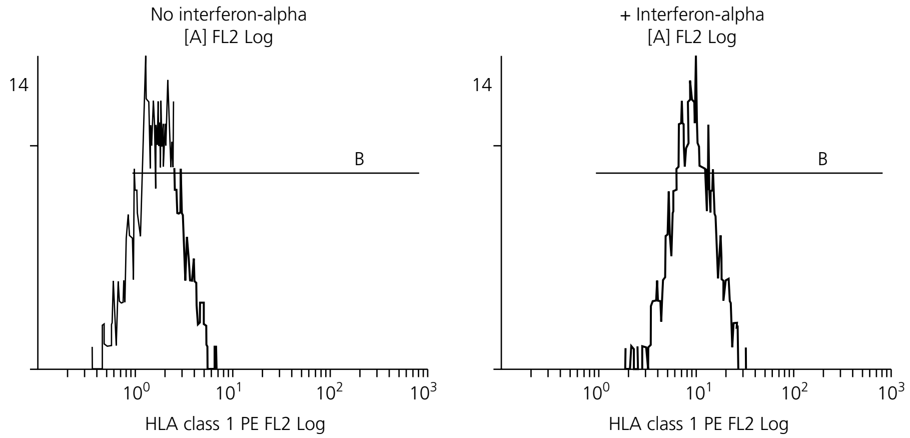

Figure 62.3 Upregulation of human leukocyte antigen (HLA) class I expression (both percent positive and mean channel fluorescence) on renal cell carcinoma cells 24 hours after exposure to interferon-alpha (10,000U/mL).

Figure 62.4 Renal cell carcinoma metastatic to the lungs (pre-transplant images a1 and a2). There was no change in metastatic disease 30 days following conditioning (b1 and b2). Following cyclosporine withdrawal, metastasis regressed completely by 110 days post-transplant (c1 and c2). The patient remains without evidence of disease over 9 years after transplantation.

during the first 2–3 years following inception of the trial; more recently, advances in our ability to manage severe or steroid-refractory GVHD have translated into a greatly reduced risk of mortality from this complication [59].

Acute GVHD has been the greatest contributor to morbidity and mortality in our RCC patients undergoing RIC HCT. Because MMF is a potent inhibitor of inosine monophosphate and has been shown in vitro to block proliferative responses of cytotoxic T cells, we added MMF to CSP as prophylaxis for GVHD in our second cohort of patients with RCC. Unfortunately, an interim analysis of the first 30 patients treated with both drugs revealed no difference in the incidence of grade II–IV or grade III–IV acute GVHD between the CSP alone and the CSP + MMF cohorts (actuarial probability of acute grade II–IV GVHD 56 and 61%, respectively). Based on these observations, we have withdrawn MMF from the transplant regimen and are currently investigating the effect of adding low-dose methotrexate (MTX) to CSP as GVHD prophylaxis.

A recent analysis of 230 patients with a variety of malignancies and non-malignant hematologic disorders undergoing RIC HCT

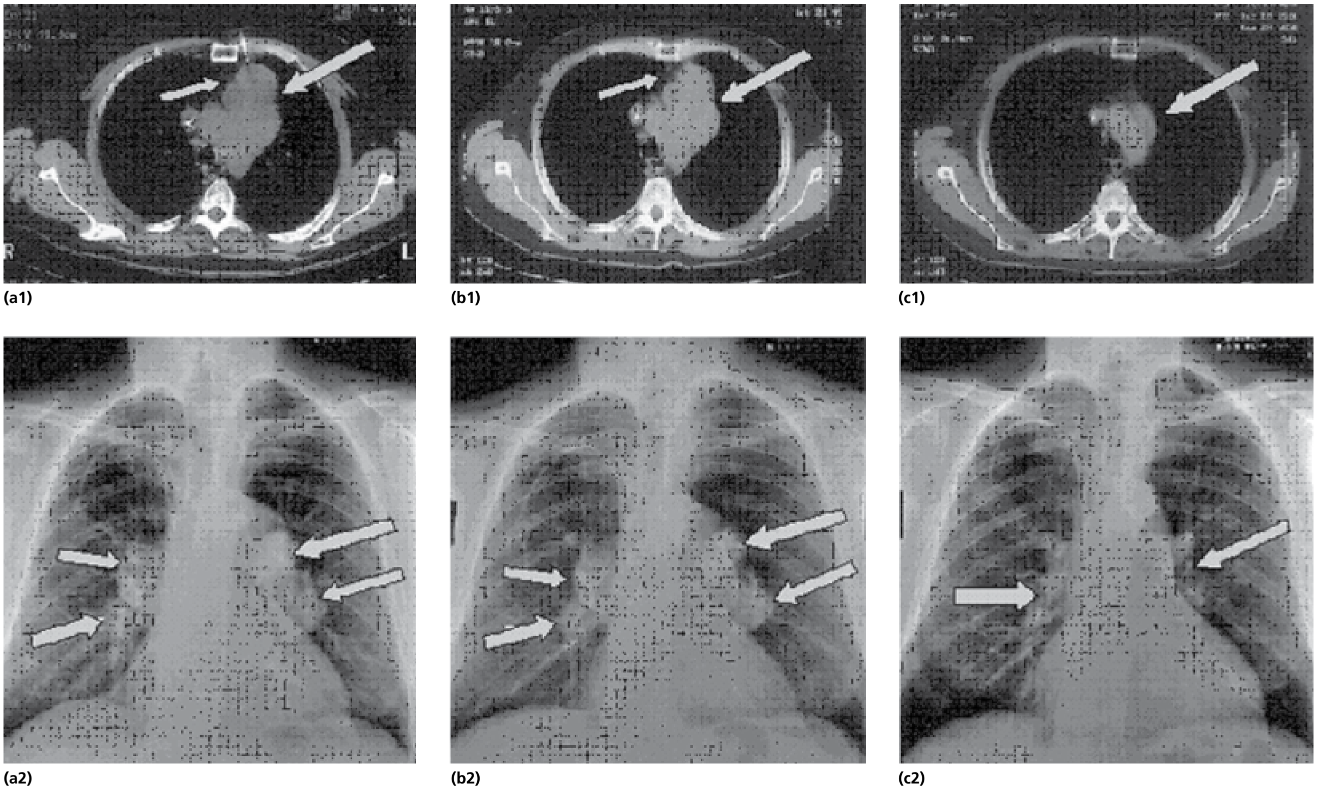

Figure 62.5 Delayed regression of renal cell carcinoma. Pre-transplant images showing bulky anterior mediastinal (a1) and hilar (a2) adenopathy. Stable disease seen 6 months post-transplant (b1 and b2). Regression of bulky adenopathy was observed 9 months post-transplant (c1 and c2).

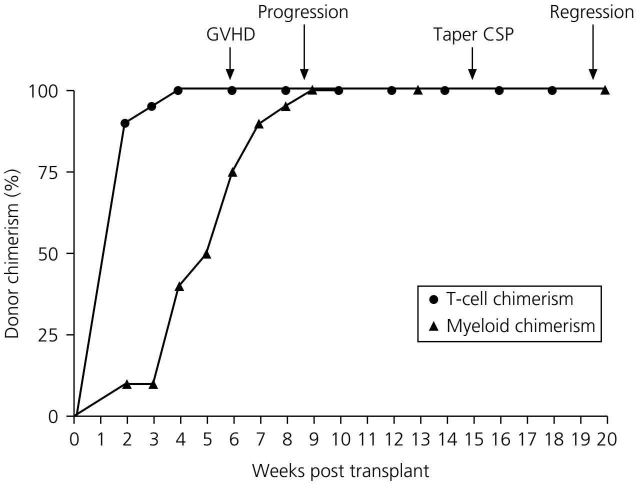

Figure 62.6 Representative lineage-specific engraftment profile following cyclophosphamide- and fludarabine-based conditioning. The percentage donor chimerism in T cells (●) and myeloid cells (▲) is shown in a patient who had a disease response 17 weeks post-transplant. CSP, cyclosporine; GVHD, graft-versus-host disease.

with cyclophosphamide and fludarabine conditioning at our institution revealed that the incidence of grade II–IV and III–IV acute GVHD was significantly less in those patients who received CSP and MTX as GVHD prophylaxis than in those who received either CSP alone or CSP + MMF. Importantly, the addition of MTX to CSP did not appear to abrogate the ability to induce GVT effects against RCC, with four of 18 patients who received this regimen demonstrating an objective response (including one patient with a CR).

Assessment of donor chimerism following RIC HCT is important not only to document the establishment of donor engraftment, but also to allow for post-transplant manipulation of the donor immune system to optimize the chances of inducing a GVT effect. In our experience, GVT effects following RIC HCT typically do not occur until the immune system has converted from mixed to predominantly donor T-cell chimerism. As a consequence, serial measurements of donor engraftment in both lymphoid and myeloid lineages are performed on all patients undergoing this approach. Representative lineage-specific engraftment profiles and their relationship to clinical outcome are shown in Figure 62.6.

Although donor T-cell engraftment typically precedes myeloid engraftment in patients receiving cyclophosphamide- and fludarabine-based conditioning, engraftment patterns may vary considerably among individual patients [60]. Several factors influence the degree and rapidity of donor engraftment, including the agents used in the conditioning regimen, the prevailing state of host immunity, and allograft cell doses. In a multivariate analysis of 36 patients with metastatic solid tumors who underwent RIC HCT at the NIH, pre-transplant exposure to chemotherapy and increased allograft CD34$^+$ cell dose were found to facilitate significantly the engraftment of donor myeloid and T cells [61]. Therefore, tailoring the intensity of RIC in solid tumor patients based on prior chemotherapy exposure seems worthy of exploration.

Although the exact mechanisms underlying the regression of metastatic RCC following allogeneic HCT are yet to be unraveled, several observations (both laboratory and clinical) suggest that an alloimmune effect mediated at least in part by donor T cells is at work (Table 62.1) [46]. The majority of patients who ultimately achieved a disease response showed early tumor growth in the first few months after transplantation, a period when the newly engrafted donor immune system was kept in check by immunosuppressive therapy or when mixed T-cell chimerism prevailed, leading to "tolerance" of host tissues (including the tumor). Tumor regression was typically delayed (4–8 months) and followed conversion to predominantly donor T-cell chimerism after immunosuppression had been withdrawn or was being tapered.

These observations highlight the importance of utilizing a transplant approach that favors rapid donor T-cell engraftment and incorporates judicious and timely withdrawal of GVHD prophylaxis. As had previously been described in patients with hematologic malignancies, a prior history of acute GVHD was associated with an increased probability of having a tumor response. One might speculate that disease regression in this setting could be the consequence of alloreactive T cells targeting mHAs that are broadly expressed on both normal tissues and tumor cells. Importantly, however, tumor shrinkage has also been observed to occur in the absence of or temporally distant from GVHD, an observation which might imply that tumor cells are particularly sensitive to allogeneic immune attack or that tumor-specific immune effectors might be involved in mediating RCC regression in some patients.

Finally, regression of RCC following a DLI or after treatment with low-dose subcutaneous IFN-α has also been observed. Disease regression after DLI suggests that the mediators of the GVT effect may be analogous to those mediating leukemia regression. Interestingly, some patients who had failed to respond to IFN-α before transplantation had disease regression when the drug was given post-transplant. This observation suggests that the mechanism by which IFN-α promotes tumor regression in the post-transplant setting relates to the ability of the drug to make the tumor a better target or enhance the allogeneic immune system rather than to a direct antineoplastic effect.

Table 62.1 Tumor response patterns consistent with a graft-versus-tumor effect after reduced-intensity conditioning hematopoietic cell transplantation

- Delayed onset of response (>100 days post-transplant)
- Response following withdrawal of immunosuppression
- Response following or concomitant with graft-versus-host disease
- Response following donor lymphocyte infusions
- Prolonged duration of response in tumors previously treatment refractory

Emerging role of RIC HCT for RCC

Although allogeneic HCT is clearly an investigational approach for the treatment of metastatic RCC, several other investigators have begun to report promising results in this disease (Table 62.2). Investigators at the University of Chicago initially reported on 15 patients undergoing HCT following a fludarabine- and cyclophosphamide-based conditioning regimen [62]. The first four patients treated were conditioned with an extremely low-intensity regimen consisting of fludarabine (90mg/m^2) and cyclophosphamide (2g/m^2) given at doses that failed to achieve adequate levels of host immunosuppression. As a consequence, three of the four patients (75%) failed to achieve stable donor T-cell engraftment and ultimately rejected their transplant. Subsequent patients received higher doses of the same conditioning agents (fludarabine 150mg/m^2 and cyclophosphamide 4g/m^2), and achieved successful and sustained donor engraftment. Of the 12 patients who engrafted and were evaluable for a disease response, four (33%) had radiographically documented disease regression consistent with a PR, including one patient who had tumor regression in his primary kidney tumor. These data have since been updated to include the first 19 patients transplanted, four of whom achieved a PR. Although all patients have relapsed at a median of 609 days following HCT, all responders were alive with a median follow-up of 41 months [compared with a median overall survival (OS) of 14 months for the entire cohort] [63].

As with other trials of RIC HCT for solid tumors, a dominant donor immune system (determined by T-cell chimerism studies) was a prerequisite for the generation of a meaningful GVT effect. Only those patients who had stable and predominantly donor immune engraftment demonstrated a disease response. In fact, one patient with graft rejection (a non-responder) underwent a second transplant with the intensified conditioning regimen, achieved complete donor engraftment, and subsequently had a PR. Only two of 12 patients (17%) experienced grade II or greater acute GVHD, perhaps the consequence of a more gradual termination of GVHD prophylaxis. Whether delaying the withdrawal of post-transplant immunosuppression will decrease the incidence of acute GVHD without negating beneficial GVT effects will need to be determined from larger studies.

A Cancer and Leukemia Group B (CALGB) intergroup trial evaluated the feasibility of performing HCT for metastatic RCC in a multi-institutional setting in the United States [64]. Twenty-two patients underwent HCT from an HLA-matched sibling donor following cyclophosphamide plus fludarabine-based conditioning.

Table 62.2 Summary of clinical trials of reduced-intensity conditioning hematopoietic cell transplantation in metastatic renal cell carcinoma

Study	Conditioning agents	GVHD prophylaxis	Acute GVHD (II–IV) (%)	Chronic GVHD (%)	TRM (%)	Response (partial or complete) (%)
Childs et al. [46] and unpublished data	CY + FLU	CSP (first 25 patients); CSP + MMF (subsequent patients)	53	21	11	53
Rini et al. [62], Artz et al. [63]	CY + FLU	Tacro + MMF	22	39	14	22

Peres et al. [103]	FLU + CY or FLU + TBI	CSP + MMF	44	38	12	32

ATG, antithymocyte globulin; BU, busulfan; CLA, cladribine; CSP, cyclosporine; CY, cyclophosphamide; FLU, fludarabine; GVHD, graft-versus-host disease; MEL, melphalan; MMF, mycophenolate mofetil; MTX, methotrexate; N/A, not available; Tacro, tacrolimus; TBI, total body irradiation; TRM, treatment-related mortality.

Seventeen of nineteen evaluable patients achieved >90% donor chimerism by day 120 after transplantation. Acute (grade II–IV) GVHD was seen in 50% of patients, and 23% of patients experienced chronic GVHD. No objective responses were seen, and median OS was only 5.5 months, with most patients dying from disease progression (with a median time to progression of 3 months). Inclusion of a number of patients with multiple adverse prognostic factors, sparing use of DLI (only two of 22 patients received DLIs despite disease progression in the majority), and inclusion of patients with non-clear cell histology are some of the factors that may account for the poor outcome observed in this trial. This trial clearly highlights the importance of appropriate patient selection and the need for identifying prognostic factors likely to predict for a favorable outcome.

The European Group for Blood and Marrow Transplantation (EBMT) reported on their experience in 124 patients with metastatic RCC undergoing HCT at multiple centers from an HLA-identical (n = 106) or partially matched (n = 5) family donor, or from an HLA-matched unrelated donor (n = 13) (Table 62.2) [65]. A variety of fludarabine-based RIC regimens were utilized. CSP alone or in combination with MMF or MTX was used for GVHD prophylaxis in the majority of patients. Durable engraftment was achieved in 121 patients. The incidences of acute grade II–IV and chronic GVHD were 40 and 33%, respectively. Twenty-eight of 98 evaluable patients had an objective tumor response, including four patients with a CR. Responses were typically delayed, with PRs and CRs occurring a median of 135 and 265 days, respectively. A short interval from diagnosis of RCC to HCT, the presence of acute GVHD, and the use of an HLA-mismatched donor were each associated with a higher probability of response. Transplant-related mortality was 16% at 1 year, and OS at 2 years was 30%. In a multivariate analysis, chronic GVHD, good performance status (Karnofsky score ≥80), DLI administration, and fewer than three sites of metastatic disease were identified as factors favorably impacting survival. The EBMT Solid Tumor Working Group also attempted to identify key prognostic factors in a study of 70 patients undergoing HCT from matched sibling donors following fludarabine-based conditioning. Performance status, LDH and C-reactive protein were identified as factors of prognostic value in a multivariate analysis; the authors were able to incorporate these variables in a Cox regression model to identify patients with poor (median OS 3.5 months) and good (OS 23 months) prognosis [66,67].

Toxicities and limitations of RIC HCT in metastatic RCC

Although there is ample evidence now to support the susceptibility of metastatic RCC to an allogeneic GVT effect, there are a number of potentially life-threatening toxicities of RIC HCT that currently limit the broader application of this approach (Table 62.3). Although the incidence of early TRM appears to be less with RIC, overall 5–20% of patients will ultimately die from a transplant-related cause.

Table 62.3 Limitations of reduced-intensity conditioning hematopoietic cell transplantation in solid tumors

	Incidence (%)
HLA-matched sibling donor available	25–30
Acute GVHD	30–60
Chronic GVHD	40–70
Cytomegalovirus reactivation	20–40
Graft rejection	5–10
Treatment-related mortality	10–20

GVHD, graft-versus-host disease; HLA, human leukocyte antigen.

Table 62.4 Patient characteristics likely to predict a favorable outcome after reduced-intensity conditioning hematopoietic cell transplantation for solid tumors

- Good performance status (Eastern Cooperative Oncology Group grade 0–1)
- Younger patient age (<65 years)
- Small tumor volume
- Slow tumor growth kinetics
- Absence of central nervous system metastatic disease
- Evidence (clinical or in vitro) that tumor is susceptible to immune-mediated attack

Infection and complications related to acute GVHD are the greatest risks associated with the procedure. In fact, three of the first 25 patients with RCC transplanted at the NIH died from GVHD-related causes [46]. Unfortunately, the addition of MMF to CSP as GVHD prophylaxis did not reduce the incidence of grade II–IV or III–IV acute GVHD. However, new second-line therapies for severe steroid-refractory GVHD such as daclizumab (monoclonal antibody directed against the alpha chain of the IL-2 receptor) and infliximab (monoclonal antibody directed against the tumor necrosis factor-alpha receptor) have shown early promise [68,69]. Our preliminary experience suggests that these monoclonal antibodies are effective in reducing mortality from steroid-refractory GVHD, particularly when given with lipid-complexed amphotericin B or voriconazole as *Aspergillus* prophylaxis, concomitant with a rapid reduction in corticosteroid dose once steroid resistance is apparent [59]. Larger studies will be required to determine whether these agents will ultimately result in a reduction in the risk of GVHD-related mortality without compromising the ability to generate a GVT effect.

Careful patient selection, with particular attention to performance status, medical comorbidities, and tumor growth kinetics may further improve transplant-related outcome. Although the use of RIC HCT for solid tumors is currently limited, preliminary clinical experience provides insight into patient characteristics that would be expected to impact favorably on transplant outcome (Table 62.4).

RIC HCT in melanoma

Despite the recent availability of novel, clinically effective immunotherapeutic and targeted approaches, the prognosis for patients with metastatic melanoma remains poor [70,71]. Nevertheless, along with kidney cancer, malignant melanoma has long shared the reputation of being an “immunoresponsive” tumor. In fact, more immunotherapy trials have been targeted at melanoma than any other solid tumor. It would seem logical, therefore, to investigate whether this tumor might be a target for a GVT effect following allogeneic HCT. Unfortunately, and rather surprisingly, the results of RIC HCT for melanoma at the NIH and at other centers worldwide have been far from inspiring.

We reviewed the outcome of 25 patients with metastatic melanoma treated at four different institutions using one of three different RIC HCT conditioning regimens: cyclophosphamide (120mg/kg) + fludarabine (125mg/m^2) (n = 18), busulfan (8mg/kg) + fludarabine (150mg/m^2) + antithymocyte globulin (ATG) (n = 5), or 200cGy total body irradiation + fludarabine (90mg/m^2) (n = 2) [72]. Engraftment was documented in 24 of 25 patients. Twelve patients (48%) developed grade II–IV acute GVHD, including 11 who had GVHD involving the skin. In 11 patients (92%), GVHD responded to immunosuppressive therapy, and one died from grade IV steroid-refractory liver GVHD. Five patients (20%) had radiographically documented disease regression consistent with a disease response (all PRs); four responses occurred in the immediate post-transplant period, likely the consequence of a chemotherapy effect, and one response was delayed in onset and occurred in association with chronic skin GVHD consistent with a GVT effect. None of the disease responses were durable, with melanoma progression occurring within 1–3 months in all responders. Six patients were treated with a DLI for tumor progression without evidence for a response. None of the 25 patients transplanted survive. Two (8%) died from transplant-related complications (acute GVHD and idiopathic encephalitis), and 23 (92%) died from progression of metastatic disease. Median survival was only 100 days (range 7–660 days), with no meaningful survival difference seen between the five responding patients (median survival 114 days) and the 20 non-responding patients (median survival 93 days).

The disappointing outcome of RIC HCT in this tumor is perplexing, particularly when clinically meaningful GVT effects in RCC have been demonstrated. Rapid tumor kinetics and bulky metastatic disease may explain at least in part why some patients failed to manifest a GVT effect. Of more concern, however, was the observation that some patients appeared to have acceleration in the pace of tumor growth in the immediate post-transplant period following RIC HCT (D. Niederweiser, personal communication). While the description of this phenomenon is admittedly subjective and could simply reflect the natural evolution of tumor growth kinetics, it is tempting to speculate that transplant-associated immunosuppression could promote tumor progression as a consequence of the destruction of innate host immune surveillance. These preliminary data demonstrate that transient conditioning-related regression of metastatic melanoma may occur following RIC HCT, although the likelihood of a clinically meaningful GVT effect appears low. The high risk of death from rapid disease progression has discouraged investigators from pursing similar RIC HCT studies in melanoma patients. Preclinical studies of “tumor-targeted” allogeneic transplant approaches are needed and, if successful, could lead to future “second-generation” RIC HCT trials in metastatic melanoma.

RIC HCT in other solid tumors

The collective global experience with RIC HCT in solid tumors other than RCC and melanoma is limited to a handful of publications, all with small patient numbers. Early enthusiasm for this approach, based on the important observation of GVT effects in patients with RCC, led to a rapid rise in the number of experimental transplants conducted for other types of treatment-refractory solid tumor. Indeed, as discussed previously, GVT effects against metastatic breast carcinoma following high-dose conditioning and allogeneic HCT have been described in some patients in association with acute GVHD [43,44]. The high prevalence of breast carcinoma in the general population, together with the disappointing results of autologous transplantation trials, inspired a number of investigators to explore RIC HCT in patients with this malignancy. Bregni et al. treated six patients with metastatic breast cancer with an RIC HCT following conditioning with cyclophosphamide, fludarabine, and thioTEPA (*N*-triethylenethiophosphoramide) [73]. Two patients had a PR that was delayed and did not occur until several months following transplantation. In both cases, responses were preceded by DLIs and GVHD, consistent with a GVT effect.

At the NCI, 16 patients with treatment-refractory metastatic breast cancer received a T-cell-depleted peripheral blood hematopoietic cell graft from an HLA-matched sibling following fludarabine and cyclophosphamide conditioning; escalating doses of DLIs were then administered on days 42, 70, and 98 post-transplant. All 15 evaluable patients achieved complete donor T-cell chimerism. Delayed responses (beyond day 28 after transplantation) consistent with a GVT effect were seen in six of 16 patients, including two patients who had experienced early disease progression following transplantation [74].

A joint International Bone Marrow Transplant Registry–EBMT registry review identified 76 patients with metastatic breast cancer undergoing allogeneic HCT between 1992 and 2000 [75]. As would be expected from the time frame of the study, a variety of both high-dose and RIC regimens were employed. Although no engraftment data were provided, approximately 51% of patients developed acute GVHD, and 25% of patients had chronic GVHD. With a median follow-up of approximately 25 months, progression-free survival in this cohort was 9%, and OS at 2 years was only 22%. The median time to progression and median OS were 8 months.

Carella et al. described a novel approach of evaluating allogeneic immunotherapy in 17 patients with breast cancer whose tumors were first maximally debulked with intensive chemotherapy followed by autologous HCT [76]. Four patients (24%) had delayed regression of metastatic breast cancer as the consequence of a GVT effect. However, in contrast to studies of allogeneic HCT alone, where only partial regression of metastatic breast cancer was typically observed, 18% of patients in this study undergoing tandem autologous/allogeneic HCT achieved long-term disease-free survival. Remarkably, three patients had delayed and complete tumor regression associated with the development of acute GVHD, and remained in remission 3.6, 4.2, and 5.9 years after transplantation. Of note, three of five patients who had partial disease regression after autologous HCT subsequently experienced a sustained CR as a result of a GVT effect, in contrast to no CRs after allogeneic HCT in the 11 patients who failed to respond to high-dose chemotherapy.

The results presented here suggest that a tandem transplant approach can induce long-term disease-free survival in a minority of patients with metastatic breast cancer. More importantly, they highlight the importance of reducing pre-transplant tumor burden to facilitate and enhance allogeneic graft-versus-solid tumor effects.

A small number of RIC HCTs have also been performed in patients with advanced ovarian cancer. One group reported delayed tumor regression in a patient with metastatic ovarian carcinoma who received an HLA-matched transplant from her sibling donor [45]. A small series of patients (n = 5) with treatment-refractory ovarian carcinoma who underwent HCT following either high-dose (one of five) or reduced-intensity (four of five) conditioning was reported by Bay et al. [77]. Three patients had regression of metastasis and/or a decrease in disease-related serum markers (i.e. CA125) early in the post-transplant period. The proximity of tumor shrinkage to chemotherapeutic conditioning makes it unclear whether these responses were truly related to an alloimmune effect. Longer follow-up and additional patients should clarify whether this tumor is indeed responsive to a GVT effect.

Another group reported the results of RIC HCT that used either cladribine or fludarabine in combination with busulfan and antithymocyte globulin in seven patients with a variety of different solid tumors [78]. Partial disease regression ascribed to a GVT effect was reported in a patient with osteosarcoma and two patients with RCC.

Since effective T-cell-mediated alloimmune responses can be generated against EBV-mediated lymphoproliferative disorders, it is tempting to speculate that EBV-mediated solid tumors may also be susceptible to GVT. Recently, Toh et al. reported their experience with RIC HCT in patients with EBV associated advanced nasopharyngeal carcinoma [79,80]. Twenty-one patients received a peripheral blood transplant from a 6/6 or 5/6 HLA-matched sibling donor following a conditioning regimen comprising cyclophosphamide, thymic irradiation, and rabbit ATG. Seven patients (33%) were reported to have a partial response, including three who had delayed and durable responses in the context of increasing donor T-cell chimerism and/or DLI administration. Patients with delayed responses also demonstrated a concomitant decrease in blood EBV DNA levels. Similar to the experience of allogeneic transplantation for RCC, the presence of GVHD was associated with a higher probability of response.

In summary, insufficient data are available at present to comment on the efficacy of RIC HCT in most solid tumors. Interpreting these limited data is made even more difficult as it is often not clear whether disease regression is related to chemotherapeutic agents in the conditioning regimen or is truly the sequela of a donor immune-mediated GVT effect. Strict adherence to criteria such as those outlined in Table 62.1 may help substantiate that a GVT effect has indeed occurred and should minimize the risk of inadvertent over-interpretation of clinical data. The efficacy of GVT in terms of its ability to induce remission varies among these malignancies, with the critical determining factors dictating neoplastic susceptibility to GVT not entirely understood.

Mechanisms underlying GVT effects in solid tumors

Disease regression following allogeneic HCT in some patients with treatment-refractory RCC has stimulated interest in exploring the mechanisms through which GVT effects occur. A better understanding of both the targets and effectors of the GVT response could lead to the development of safer and more efficacious transplant regimens. Based on clinical data and our knowledge of the mediators of the GVT effect, T-lymphocytes (both $CD8^+$ and $CD4^+$) and natural killer (NK) cells probably play a role in mediating immune responses against solid tumors [81–85]. The observation that disease regression (1) is associated with an increase in the percentage of circulating $CD8^+$ T cells with an activated phenotype ($DR^+CD38^+CD57^+$), (2) does not occur until T-cell chimerism is predominantly donor, and (3) sometimes follows a DLI provides strong evidence to support this hypothesis [46,86].

What, if any, role allogeneic NK cells play in mediating GVT effects in solid tumors is currently unknown. Researchers have shown that NK cells may play a critical role in mediating GVT effects in patients with acute and chronic myelogenous leukemia undergoing transplants from haploidentical donors with killer immunoglobulin-like receptor (KIR) incompatibility in the GVHD direction (i.e., patient Cw allele mismatched to donor and therefore unable to function as a ligand for donor NK cell KIR) [87,88]. We have conducted in vitro experiments showing that NK cell clones generated from KIR-mismatched allogeneic donors can kill both melanoma and RCC tumor cells preferentially through KIR incompatibility [89]. These preliminary data suggest that the antitumor effects seen against acute myelogenous leukemia following KIR-incompatible allogeneic HCT might also occur against select solid tumors in the setting of haplotransplantation.

A retrospective analysis in a subset of patients with metastatic RCC who underwent a T-cell-replete RIC HCT from an HLA-matched sibling donor at the National Heart, Lung, and Blood Institute provides preliminary clinical evidence in support of this hypothesis [90]. In this study, KIR incompatibility (defined as the presence of one or more KIR genotypes in donor cells for which the corresponding inactivating HLA-B or -C ligand is missing from the recipient) appeared to predict higher objective response rates and also improved overall survival, an effect most pronounced in patients lacking HLA-Bw4 who received a transplant from donors with genotypic evidence of KIR3DL1.

The identification of target antigens involved in GVT effects is an area of intense investigation, and recent findings suggest that both lineage-restricted and broadly expressed mHAs are potential targets. In an attempt to clarify the role of mHAs in alloimmune T-cell responses against RCC, previously characterized mHA-specific CTL clones were tested for cytotoxicity against EBV-transformed B cells (EBV-LCLs) (HLA matched for the appropriate mHA-restricting allele) first to identify RCC patients expressing the relevant antigen. Subsequently, CTLs recognizing patients' EBV-LCLs were tested for their ability to recognize mHAs present on patient RCC cells. In the majority of cases, CTLs recognizing patient EBV-LCLs also recognized patients' RCC cells, suggesting that broadly expressed mHAs could serve as targets for immune-mediated tumor regression in the setting of acute GVHD [91].

Preliminary data obtained from patients with RCC regressing after allogeneic transplantation suggest that the target antigens may differ in those who experience tumor regression in the context of GVHD as opposed to those without. T-cell clones that specifically lysed patient RCC cells or both RCC and patient hematopoietic cells were isolated and expanded from one responder where a GVT effect occurred in the absence of GVHD. In contrast, we could only expand T-cell clones that reacted against both tumor and hematopoietic cells in a patient who had disease regression that occurred in the setting of acute GVHD [86]. Hence it is conceivable that cellular immune responses directed against antigens shared by tumor and normal tissues would result in GVHD in addition to GVT, whereas GVT without GVHD would be expected to occur in those having a cellular immune response against tumor-restricted antigens (Figure 62.7).

The identity of antigens that serve as targets for a GVT effect, specifically those that appear to be restricted to the tumor, could provide clues to the intricate mechanisms of GVT and provide valuable insight that might aid in the development of future tumor-targeted immunotherapeutic approaches. Using T cells isolated from a patient who had regression of metastatic RCC following allogeneic transplantation, we recently identified a new solid tumor antigen that appears to be overexpressed in the majority of kidney tumors. $CD8^+$ T-cell clones isolated from lymphocytes obtained from this patient after transplantation and following tumor regression lysed the patient's RCC cells in vitro. Using complementary DNA expression cloning, the target antigen of these allogeneic T cells (donor in origin) was found to be a 10-mer peptide tumor antigen that was recognized in the context of HLA-A11. The genes encoding this antigen (HERV-E) were found to be derived from a human endogenous retrovirus that was found to be overexpressed in more than 50% of clear cell carcinomas but not in any normal tissues [58]. Remarkably, HERV-E expression was found to be restricted to the clear cell subtype of RCC (ccRCC), which at present is the only histological subtype of kidney cancer where GVT effects have been observed. Clear cell RCC is characterized by an inactivation of the von Hippel–Lindau (*VHL*) tumor suppressor gene with subsequent stabilization of hypoxia-inducible transcription factors HIF-1α and -2α. Recent data show that expression of HERV-E is associated with *VHL* inactivation and appears to be regulated by hypoxia-inducible factor 2α (HIF2α); HERV-E expression in ccRCC was found to

Figure 62.7 Immune populations hypothesized to contribute to graft-versus-tumor (GVT) effects following reduced-intensity conditioning hematopoietic cell transplantation. Minor histocompatibility antigens (mHAs) are either restricted to the tumor or broadly expressed on normal and malignant tissues. Tumor cells need to express a dominant natural killer (NK) cell receptor-activating ligand (i.e., MICA) to initiate NK cell-mediated killing. GVHD, graft-versus-host disease; MHC, major histocompatibility complex; NKL, natural killer ligand; TAA, tumor-associated antigen.

correlate linearly with HIF-2α levels and could be silenced in tumor cells by transfection of normal *VHL* or by siRNA inhibition of HIF-2α [92]. Using chromatin immunoprecipitation, HIF-2α was found to serve as transcriptional factor for HERV-E by binding with HIF response elements (HREs) localized in the HERV-E 5′LTR. These data provide the first evidence that inactivation of a tumor suppressor gene can result in aberrant proviral expression in a human tumor that may have the net effect of enhancing the immunogenicity of clear RCC.

These studies provide the first insights into the mechanisms accounting for the selective expression of a HERV in a solid tumor, demonstrating that inactivation of a tumor suppressor gene can result in aberrant expression of a highly immunogenic provirus in ccRCC. The antigen encoded by this HERV-E is the first solid tumor antigen identified using allogeneic T cells from a patient undergoing HCT, and could provide a potential target for cellular immunity against RCC both within and outside the context of allogeneic HCT.

Future directions

The lack of efficacy of chemotherapeutics, radiotherapy, and cytokine-based immunotherapy for many patients with metastatic cancer has catalyzed enthusiasm for exploring allogeneic immunotherapy against solid tumors. While there is little doubt about the potential for its application in oncology, extensive use of RIC HCT in the treatment of solid tumors will likely remain limited until both the safety and efficacy of the approach are improved. Further progress in the fields of tumor vaccination and adoptive “tumor-targeted” T-cell infusion are needed to address these problems. Recently, murine models have demonstrated that tumor-specific immunity can be boosted following post-transplant tumor immunization. In an MHC-matched but mHA-disparate allotransplant model, immunization of the recipient post-transplant against either leukemia or fibrosarcoma resulted in enhanced antitumor activity without exacerbating GVHD [93]. A similar strategy could be used in humans for those patients who fail to achieve a CR after RIC HCT. Likewise, adoptive transfer of ex vivo-expanded tumor-specific CTLs that are generated from the donor could be used to enhance a GVT effect. Recent developments in our understanding of the role played by NK cells in both enhancing GVT effects and minimizing GVHD offer the prospect of incorporating “KIR-incompatible” or “KIR-mismatched” NK cell therapy into allogeneic immunotherapy strategies.

In vitro, allogeneic KIR-incompatible NK cells have enhanced cytotoxicity against RCC cells compared with autologous or KIR-matched NK cells [89]. The adoptive infusion of alloreactive donor NK cells has been found to reduce significantly the risk of acute GVHD and potentiate graft-versus-RCC effects in a murine model of HCT for kidney cancer [94]. Trials evaluating adoptively infused allogeneic NK cells and other novel methods to direct or target alloimmune cells against RCC in humans undergoing HCT for metastatic RCC will likely be explored in the near future.

The identification of transcripts derived from a HERV-E restricted to clear cell kidney tumors that encode immunogenic peptides capable of inducing cellular immune responses in patients with RCC after transplantation remains a promising area of investigation for the development of transplants targeting donor immunity against the tumor. Peptides derived from the *env* region of this HERV-E, which is also expressed in clear cell RCC, have recently been identified that have high binding affinity for HLA-A*0201, are immunogenic in vitro, and stimulate antigen specific CD8+ T cells that recognize ccRCC cells in an HLA-A*0201- restricted fashion [95]. These data suggest that antigens derived from this newly discovered HERV-E envelope could represent excellent targets for T-cell-based immunotherapy for kidney cancer. Because HERV-E expression appears to be restricted to kidney cancer, one could conceive of a future approach where donor T cells, stimulated ex vivo by HERV-E-derived peptides, are infused post-transplant to bolster a GVT effect specifically against the tumor.

A variety of novel "targeted" agents have recently been approved for the treatment of several malignancies. Several inhibitors of the VEGF pathway are now available for the treatment of metastatic RCC. Although unlikely to be curative, these agents have been shown to prolong progression-free survival. Since heavy disease burden and rapidly progressive tumors can significantly detract from the ability to generate clinically meaningful GVT responses, incorporating the aforementioned disease-stabilizing antiangiogenic agents into HCT strategies might be beneficial and should be explored.

CHAPTER 63

Hematopoietic Cell Transplantation for Neuroblastoma

Justin T. Wahlstrom and Katherine K. Matthay
University of California School of Medicine, San Francisco, CA, USA

Introduction

Neuroblastoma is a malignancy of young children derived from embryonic neural crest cells of the peripheral sympathetic nervous system. It is the most common extracranial solid tumor of childhood, with approximately 730 new cases per year in the United States, and accounts for 15% of cancer-related deaths in children [1]. Some of its unique features, such as the ability to secrete and store catecholamines, its inherent genetic heterogeneity, and its propensity to undergo differentiation either spontaneously or with various stimuli, have led to novel diagnostic and therapeutic approaches. As therapy has become more tailored to biologic and clinical risk groups, a higher proportion of children with neuroblastoma are surviving. However, nearly half of all children with neuroblastoma present after 1 year of age with metastatic disease; of these, less than 40% will survive more than 5 years, even with aggressive combination therapeutic approaches [2]. The goals of future therapy are to increase the specificity of treatment in order to improve the survival of children with advanced disease, while reducing therapy-related toxicity.

Clinical presentation and staging

Neuroblastoma can originate from any site in the sympathetic nervous system, presenting as a mass in the abdomen, mediastinum, neck, or pelvis. The most common primary site (in 70% of cases) is the abdomen (often arising from the adrenal gland); mediastinal tumors are more common in infants than in older children. Masses arising from the organ of Zuckerkandl in the pelvis can present with constipation and bladder dysfunction. High thoracic or cervical masses can cause Horner syndrome [3]. Epidural or intradural extension of tumor occurs in 5–16% of neuroblastoma cases. These patients may have symptoms associated with spinal cord compression. Prompt administration of chemotherapy appears to be effective for treating intraspinal neuroblastoma, and it may avoid some of the long-term sequelae associated with either radiation or surgical resection and laminectomy [4].

Metastatic neuroblastoma can classically present with proptosis and periorbital ecchymoses, and bone pain resulting in irritability and limp. Rapid enlargement of liver metastases can result in respiratory compromise, particularly in neonates. Skin lesions, seen almost exclusively in infants, have a bluish hue and have been given the nickname "blueberry muffin" lesions. Rarely, neuroblastoma will present with a paraneoplastic syndrome, including either watery diarrhea caused by secretion of vasoactive intestinal peptide, or opsoclonus–myoclonus–ataxia syndrome, characterized by jerky multidirectional eye movements, loss of balance, and intermittent muscle jerks [5]. The latter syndrome is thought to be caused by the production of antineuronal antibodies that cross-react with normal neural epitopes [6].

The previous International Neuroblastoma Staging System (INSS) [7] was based on extent of surgical excision, but the newly agreed upon International Neuroblastoma Risk Group Staging System (INRGSS) is based on the presence or absence of image-defined risk factors, which generally consist of encasement or invasion of vital organs, nerves, and vessels [8]. Staging alone is predictive of event-free survival (EFS) at 5 years (Table 63.1).

In addition to diagnostic studies such as bone marrow aspiration, histology, quantification of urine or serum catecholamines, and imaging by computed tomography, iodine-123-labeled *m*-iodobenzylguanidine ([^{123}I]MIBG) scintigraphy is mandatory for all patients, and should be performed prior to tumor excision. MIBG is a guanethidine derivative that is an analog of norepinephrine, and taken up in 90% of neuroblastomas. One unequivocal MIBG-positive lesion at a distant site is sufficient to define metastatic disease. Technetium-99m bone scintigraphy has largely been supplanted by [^{123}I]MIBG, but may be required if MIBG positivity of the primary tumor cannot be confirmed, although now [^{18}F]deoxyglucose positron emission tomography is preferred as superior to bone scan [9]. MIBG scans should be performed in all high-risk patients at diagnosis, prior to high-dose myeloablative therapy, and before and after therapy given for minimal residual disease (MRD). Interpretation of MIBG scans relies on a standardized semiquantitative scoring system, which allows for inter-institutional comparison. The Curie extension score is currently being used in large prospective phase III Children's Oncology Group (COG) trials for high-risk neuroblastoma in North America [9].

Tumor molecular biology

Amplification of the *MYCN* oncogene on chromosome 2p24, found in 25% of neuroblastoma cases, is the most consistent unfavorable genetic change, and is independent of age, stage, and other biologic characteristics. It is an essential component of risk assessment that can easily be measured by fluorescent in situ hybridization (FISH) on primary tissue or bone marrow tumor. Chromosomal gain at 17q without extensive amplification may

be found in neuroblastoma in 50–60% of cases, and may portend a worse outcome [10].

Neuroblastomas may be diploid or hyperdiploid, and chromosomal content by measurement of DNA index has established that near-diploid DNA content is less favorable and associated with other adverse prognostic markers [11]. Allelic losses of 1p and 11q are common in neuroblastomas, and both predict adverse outcome [12]. The presence of any segmental chromosomal alterations [as detected by array comparative genomic hybridization (CGH)] has now been shown to be an independent adverse risk factor in neuroblastoma [13]. In addition, linkage analysis studies of familial neuroblastoma have identified germline mutations in the anaplastic lymphoma kinase (ALK) gene, and ALK mutations or amplifications have subsequently been identified in approximately 8% of all sporadic neuroblastoma tumors. Germline mutations in the ALK tyrosine kinase may be a main cause of familial neuroblastoma, and may represent a potential therapeutic target [14].

Risk classification and treatment approach

In an effort to optimize risk stratification internationally, the INRG classification schema was published in 2009 [15]. This system takes into account the optimal age cut-off of 18 months, image-defined INRGSS staging, *MYCN* amplification, histologic category, tumor grade, ploidy, and genetic aberrations of 11q (Table 63.2). Very low-risk tumors are generally managed with surgery alone, unless symptomatic cord compression or respiratory compromise necessitates a short course of chemotherapy. Patients in the low-risk group with Stage 1 or 2 disease have an expected 4-year survival of >95% with surgery only [16], whereas infants with Stage 4S disease have >90% survival with supportive care or a short course of chemotherapy [17]. The smaller intermediate-risk group generally requires multiple cycles of a modest outpatient chemotherapy regimen and often requires surgical resection, but the chemotherapy can safely be reduced to 3–6 cycles while maintaining a 3-year EFSl of >90% [18]. With aggressive therapy, long-term survival for high-risk neuroblastoma has only recently risen above 15% to a 3-year EFS of 30–40%. Despite advances, much still needs to be done to improve outcome (Figure 63.1).

Table 63.1 International Neuroblastoma Risk Group staging system

Stage	Description	Estimated 5-year EFS (%)
L1	Localized tumor not involving vital structures as defined by the list of image-defined risk factors and confined to one body compartment	90
L2	Locoregional tumor with presence of one or more image-defined risk factors	78
M	Distant metastatic disease (except stage MS)	35
MS	Metastatic disease in children younger than 18 months with metastases confined to skin, liver, and/or bone marrow	83

Treatment of high-risk neuroblastoma

Therapy for high-risk neuroblastoma is currently divided into three phases: intensive induction treatment, marrow ablative therapy, and management of MRD. The goal of induction therapy is to achieve maximum reduction of tumor burden, including reduction of bone marrow tumor (in vivo purging), within a time frame that will minimize the risk of developing resistant tumor clones and clinical progression. Subsequently, very high-dose myeloablative therapy may be used to try to overcome residual and potentially resistant tumor and is followed by autologous hematopoietic cell transplantation (HCT). The relapse rate of >40% even after such treatment [19] has led to the approach of using tumor-targeted therapies following high-dose conditioning in an effort to eliminate microscopic resistant clones (MRD).

Induction therapy

Current standard induction chemotherapy usually includes 5–7 cycles of combination chemotherapy, including high-dose alkylators and a platinum derivative, along with surgery to bulky tumor sites. Induction regimens used in large cooperative studies have shown overall response rates, including complete and partial remission (CR + PR), ranging from about 60 to 90% at the end of 5–6 months of treatment [2,20]. Most regimens also include surgery to residual disease, although the overall impact of complete resection on survival in Stage 4 disease is still uncertain.

Table 63.2 Current Children's Oncology Group neuroblastoma risk classification

INRG stage	Age (months)	Histologic category	Grade of tumor differentiation	*MYCN*	11q aberration	Ploidy	Pretreatment risk group	
L1/L2		GN maturing; GNB intermixed					A	Very low
L1		Any, except GN maturing or GNB intermixed		NA			B	Very low
				Amp			K	High
L2	<18	Any, except GN maturing or GNB intermixed		NA	No		D	Low
					Yes		G	Intermediate
	>18	GNB nodular; neuroblastoma	Differentiating	NA	No		E	Low
					Yes		H	Intermediate
			Poorly differentiated or undifferentiated	NA				
				Amp			N	High
M	<18			NA		Hyperdiploid	F	Low
	<12			NA		Diploid	I	Intermediate
	12 to <18			NA		Diploid	J	Intermediate
	<18			Amp			O	High
	>18						P	High
MS	<18			NA	No		C	Very low
					Yes		Q	High

Figure 63.1 Event-free survival of children <21 years of age by era of diagnosis. Source: Moroz et al. 2011 [37]. Reproduced with permission of Elsevier.

Single institutional studies have demonstrated that further dose intensification of alkylating agents and cisplatin resulted in complete and very good partial remission (VGPR) rates of up to 85% [21,22]. This Memorial Sloan Kettering Cancer Center (MSKCC) N7 induction regimen consisted of cyclophosphamide, doxorubicin, and vincristine, alternating with cisplatin and etoposide, with good response in 21/24 patients. These excellent results however, could not be reproduced by a UK pilot study of 47 patients [23] nor by the French Society of Pediatric Oncology [24].

The large cooperative COG trial A3973 using the same regimen in 489 patients also resulted in a CR/VGPR rate of only 52%, with PR 26%, for overall response rate similar to those with previous protocols [25]. In comparison, the European study comparing a dose-intensive induction (rapid COJEC) with standard induction therapy (OPEC/OJEC) showed that although there was no detectable improvement in overall survival (OS), the 5-year EFS was significantly higher in patients receiving rapid COJEC induction (30.2% vs. 18.2%, $p = 0.02$) [26].

Some studies have also investigated newer single agents such as carboplatin and topotecan in newly diagnosed neuroblastoma, using the “up-front phase 2 window.” Following two courses of single-agent therapy prior to induction treatment, response rates (CR + PR) of >30% have been observed, with no evidence that the window design adversely affected outcomes [27]. A pilot induction regimen incorporating pharmacokinetically guided dose-intensive topotecan together with cyclophosphamide prior to four cycles of multiagent therapy, tested in 31 patients, demonstrated that the regimen was well tolerated and produced a tumor response in 84% of patients following induction; 3-year EFS and OS were 37.8 and 57.1%, respectively [28]. This pilot then provided the basis for the recently completed phase 3 COG ANBL0532 study.

Local control

Despite surgical resection of the primary tumor, recurrence in the local or regional area of primary disease is a component of relapse in a large proportion of children with high-risk neuroblastoma, at rates ranging from 20 to 80% in reports that often include local radiotherapy and myeloablative therapy [2,19,29]. Studies in Stage 4 disease utilizing radiotherapy administered to the primary tumor bed either before or following myeloablative conditioning suggest a lower local recurrence rate using radiotherapy in retrospective analysis, but the variability in extent of resection makes these difficult to interpret [29]. Retrospective analysis of the local control in the CCG 3891 study showed a benefit for local radiotherapy to residual disease for patients undergoing HCT.

Pilot studies have also been reported using higher focal radiation via intraoperative radiotherapy (IORT) in order to spare normal organs [30]. One retrospective study has lent support to the therapeutic value of IORT while avoiding the associated toxicities of external beam radiotherapy [31]. However, this benefit must be balanced by the occasional occurrence of hypertension and vascular stenosis. More recently, pilot studies have reported the use of proton beam radiotherapy, which adds precision but has the potential disadvantage of incomplete treatment of margins [32]. In addition, pilot studies in Europe have suggested that treatment prior to chemotherapy induction with the targeted radiopharmaceutical [^{131}I]MIBG rapidly reduces primary tumor bulk and facilitates later resection [33]. Although the particular modality may be debated, the current standard therapy of high-risk neuroblastoma continues to include radiotherapy to the primary tumor bed and residual metastatic sites [34,35].

Autologous hematopoietic cell rescue

The observed linear–log relationship between drug dose and tumor cell cytotoxicity for alkylating agents suggested that if the drug dose could be increased without increasing toxicity, then a multiple log increment in tumor cell killing could be achieved. The demonstration that hematopoiesis could be restored with autologous hematopoietic cells allowed the use of much higher doses of chemotherapy with autologous bone marrow support for the treatment of solid tumors. Early pilot studies showed that responses were seen in children with resistant neuroblastoma after high-dose chemoradiotherapy and bone marrow reinfusion [36]. Comparison of long-term survival for children with neuroblastoma in the premyeloablative era, and after 1990, a time when high-dose therapy with HCT became routine for many of these patients, showed a significant difference in outcome (Figure 63.1) [37].

Subsequent single-arm studies in the United States and Europe verified an apparent improvement in outcome for autologous HCT compared retrospectively with results for chemotherapy. The single-arm studies containing more than 20 patients that have been reported are summarized in Table 63.3. The 3-year EFS in these studies varied from 24 to 50%. Comparison between studies in this table is fraught with pitfalls, because EFS is sometimes estimated from time of transplant, which differs from 4 to 10 months from diagnosis, and in a few studies from time of diagnosis. The patient groups also differ in whether they were comprised of only Stage 4 patients >1 year at diagnosis or also included other high-risk patients.

Non-randomized comparisons of autologous HCT with chemotherapy

Several cooperative pediatric groups have attempted statistical non-randomized comparisons of outcomes for groups of patients treated either with conventional doses of chemotherapy or high-dose conditioning chemotherapy, total body irradiation (TBI), and purged

autologous HCT, with differing conclusions. In an effort to avoid the bias introduced by comparing therapies from two different time periods, outcomes from two contemporaneous Pediatric Oncology Group (POG) studies were compared: POG 8441 (surgery plus conventional chemotherapy) and POG 8340 (elective autologous HCT pilot protocol). There was no significant prognostic benefit of switching in remission from the chemotherapy protocol to the transplant protocol ($p = 0.91$) [38].

The Children's Cancer Group (CCG) examined the outcome of Stage 4 patients >1 year of age treated with identical induction chemotherapy on a CCG pilot protocol, who then either continued on the same chemotherapy ($n = 73$) for 1 year (CCG-321P2), or proceeded to trial CCG-321P3 with myeloablative chemotherapy, TBI, and purged autologous HCT ($n = 94$) [39]. The decision to use autologous HCT was non-random and depended on parental, investigator, and institutional choice. The advantage for autologous HCT versus chemotherapy was significant for the group as a whole, with 3-year EFS of 40 and 19%, respectively, different from the findings of the POG studies. The advantage for autologous HCT was greatest for certain very high-risk subgroups, including those >2 years of age at diagnosis, those with bone or bone marrow metastases, those with *MYCN* gene amplification, and those who had only a PR rather than CR to the first 4–6 cycles of induction chemotherapy. These and other studies, and also the overall improvement in survival for high-risk neuroblastoma seen in the era after introduction of HCT, led to several randomized clinical trials.

Randomized comparison of autologous HCT with standard-dose chemotherapy

The European Neuroblastoma Study Group (ENSG) performed the first randomized study comparing high-dose conditioning treatment with conventional chemotherapy. This study, open from 1983 to 1985, was a comparison of high-dose melphalan with no further therapy after induction, and showed a significant advantage in progression-free survival (PFS) for those patients with Stage 4 disease >1 year of age at diagnosis undergoing high-dose therapy (5-year EFS 33% vs. 17%, $p = 0.01$; 5-year OS 46% vs. 21%, $p = 0.03$). However, only 59% of patients were randomized, so the group as a whole excluded the highest risk patients, and bias may have been introduced. Long-term follow-up of the ENSG-1 was published in 2005 for a median of 14.3 years from randomization [40]. The median time to relapse for the melphalan versus the "no melphalan" group was unaltered at 18 months versus 3 months. Despite the limitations of the study, the survival improvement achieved at 5 years appears sustained at 14 years (Figure 63.2a).

At the time of publication of the initial promising European results, the CCG launched a larger randomized study in the United States comparing high-dose chemotherapy and TBI followed by purged autologous HCT with intensive non-myeloablative chemotherapy as the continuation regimen following induction, surgery, and radiation [2]. The results clearly showed a significant improvement in EFS for the patients randomly assigned to autologous HCT, both by an intent-to-treat analysis and also by treatment received (Figure 63.2b). As in the previous CCG non-randomized comparison, the highest

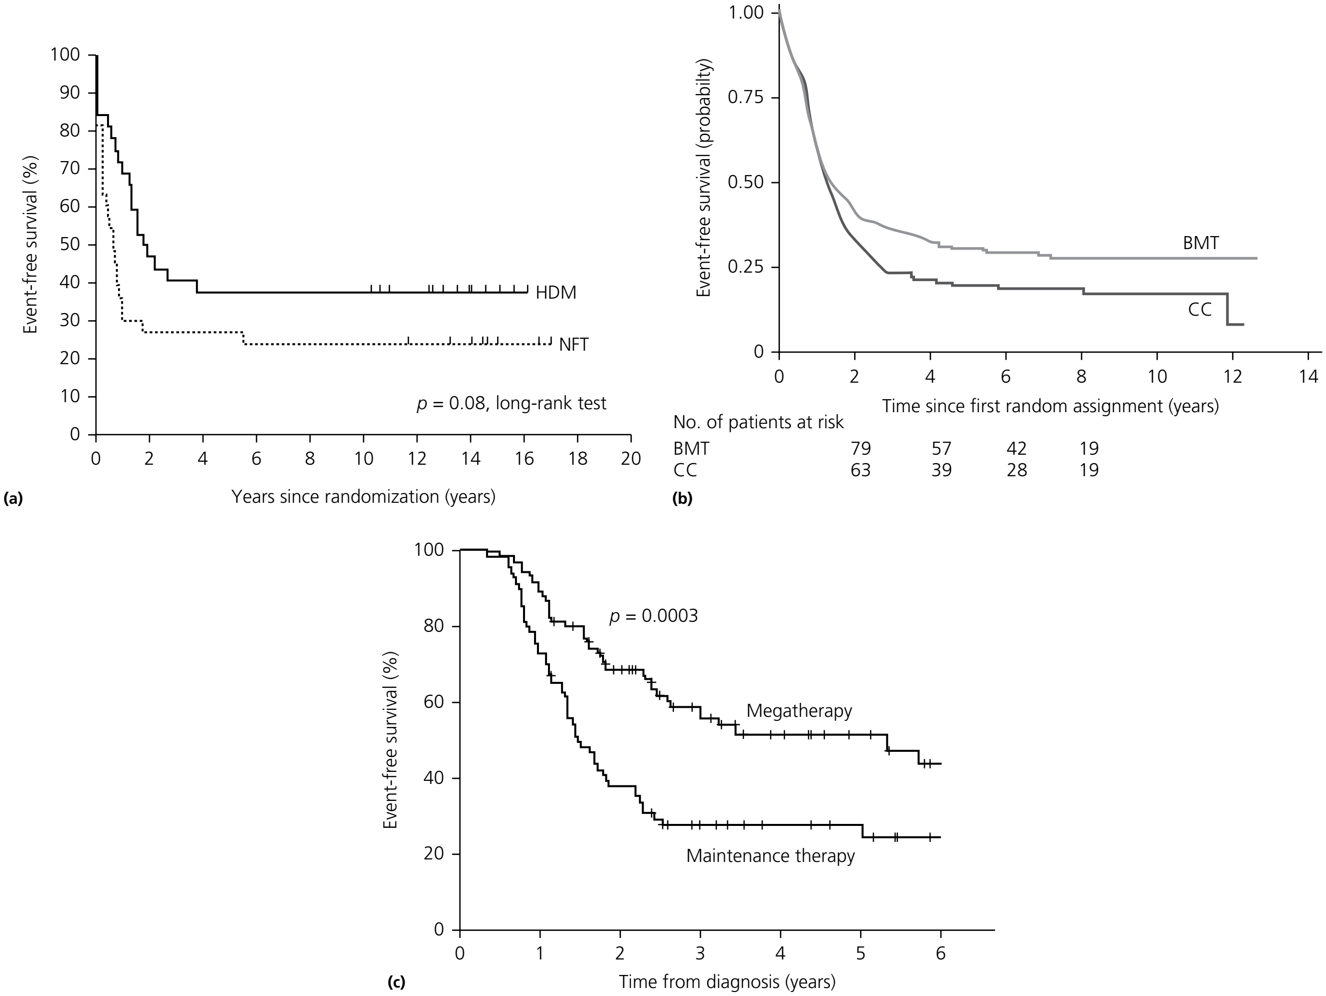

Figure 63.2 Outcomes of randomized trials comparing hematopoietic cell transplantation to no further therapy or chemotherapy for high-risk neuroblastoma. (a) High-dose regimen: high dose melphalan. Transplant group: $n = 32$ with 5-year EFS = 38% (95% CI 21–54%). No melphalan group: $n = 33$ with 5-year EFS = 27% (95% CI 12–42%); $p = 0.08$. Source: Pritchard et al. 2005 [40]. risk patients, those with *MYCN* amplified tumors, or those >2 years of age at diagnosis had the most significant benefit. In addition, there was no significant difference in toxic deaths between patients randomized to either arm, and the hospital days were identical, helping to validate the cost-effectiveness of this treatment. More recent analysis of continued follow-up of a median of 8 years on this study showed a significant advantage in 5-year survival for the patients randomized to the autologous HCT arm ($p = 0.004$) [41].

The most recent randomized study to compare myeloablative therapy against continued chemotherapy was a German cooperative study that enrolled 339 patients from 1997 to 2002 [42]. Patients ($n = 295$) were randomized to receive either myeloablative "megatherapy" and autologous HCT or maintenance with oral cyclophosphamide. The myeloablative regimen consisted of melphalan, etoposide, and carboplatin. This was followed by either immunotherapy with chimeric anti-GD2 monoclonal antibody given for 1 year or oral isotretinoin for 6 months. In accordance with the CCG study, EFS was significantly increased in the patients receiving myeloablative therapy and autologous stem-cell rescue (Figure 63.2c). Potential confounders in this study included variable time of randomization, variations in treatment regimens prior to transplant, timing of surgery and stem-cell collection, and high crossover rates.

High-dose conditioning regimens

The first high-dose regimen used in the treatment of neuroblastoma was single-agent high-dose melphalan. This progressed to various combinations of other agents, including cisplatin, etoposide and doxorubicin, melphalan with busulfan, and melphalan with carboplatin and etoposide. Other centers used a thioTEPA (*N*-triethylenethiophosphoramide) base, coupled with cyclophosphamide or etoposide, or busulfan combined with cyclophosphamide. More recently, attempts have been made to incorporate topotecan into the conditioning regimen in combination with thioTEPA and etoposide [43]. A retrospective analysis by the EBMT failed to show any difference in EFS using different high-dose regimens [44–46].

On the other hand, an analysis by the Institut Gustave-Roussy showed that patients treated with busulfan and melphalan appeared to have better EFS than those on other conditioning regimens at a single institution [47]. These data may depend on the chronology of the protocols and also the fact that the busulfan regimen was compared with a combination of a variety of other regimens. The ENSG is currently conducting a large, multinational cooperative randomized study (the HR-NBL1 trial) comparing the COG regimen of carboplatin, etoposide, and melphalan (CEM) with the busulfan and melphalan (BuMel) regimen [48]. Preliminary results demonstrated a significant difference in 3-year EFS from time of transplant in favor of the BuMel regimen (49% vs. 33%, $p < 0.001$). This was primarily related to the decreased incidence of relapse and progression observed with this regimen. In addition, despite the occurrence of sinusoidal obstructive syndrome (18% incidence) associated with the BuMel regimen, the severe toxicity rate (ICU and toxic deaths) was significantly higher for the CEM than the BuMel regimen. Owing to the superiority of BuMel that was demonstrated in this trial, it has become the recommended conditioning regimen administered to high-risk neuroblastoma patients prior to autologous HCT in Europe and is now being tested in North America in pilot studies.

Tandem transplants

Tandem transplantation uses repetitive high-dose therapies followed by HCT to provide further increases in dose intensity. Several groups have investigated whether this translates to improved outcomes in high-risk neuroblastoma. George et al. reported an updated compilation of the limited institution experience with a tandem transplantation protocol [49]. The first high-dose therapy employed a regimen of etoposide, carboplatin, and cyclophosphamide, and the second included melphalan and TBI. An average of 7.2×10^6 $CD34^+$ cells/kg were available to support each cycle. Ninety-seven high risk patients were treated with five cycles of chemotherapy followed by two courses of myeloablative therapy and hematopoietic cell rescue. The 5-year PFS from diagnosis for all patients was 47% [95% confidence interval (CI), 36–56%].

Following this, a pilot study by the POG tested the feasibility and safety of tandem transplantation in a cooperative group setting using alternating courses of cisplatin/etoposide, cyclophosphamide/doxorubicin/vincristine, and ifosfamide/etoposide during induction, followed by etoposide, carboplatin, and cyclophosphamide conditioning for autologous HCT #1, and thioTEPA and cyclophosphamide (Thio/CY) conditioning for autologous HCT #2. The results of this study showed that this regimen is feasible in terms of transplant-related mortality and stem-cell collection. PFS from diagnosis was 24.2 ± 7.5% at 5 years [50]. To address better the question of whether two tandem transplants produce superior outcomes compared with a single transplant, the COG phase 3 randomized trial ANBL0532 compares the efficacy of a single transplant using CEM with two tandem transplants using Thio/CY followed by CEM. The study closed to accrual in 2012 and data are being collected.

Targeted radionuclides as part of high-dose therapy

The use of targeted radionuclides allows the delivery of very large radiation doses to the tumor with less radiation to normal organs. Targeted radioisotope therapy using anti-GD2 antibody or MIBG for delivery of radiation in the form of iodine-131 has been tested extensively in clinical trials in relapsed neuroblastoma [21]. [^{131}I]MIBG has been widely shown in European and US studies to elicit a 30–40% response rate for refractory and relapsed neuroblastoma in phase I and II studies [51,52]. The main toxicity has been hematologic, which has been abrogated with stem-cell infusion [53]. Several recent studies have investigated MIBG at higher dose levels and combined with other agents, including standard chemotherapy and myeloablative therapy, demonstrating the feasibility of this approach.

The results of these studies argue strongly for the incorporation of [^{131}I]MIBG therapy into regimens that include chemotherapeutic agents. A phase I study incorporated escalating doses of [^{131}I]MIBG followed by carboplatin, etoposide, and melphalan with hematopoietic stem-cell infusions [54]. The combination appeared feasible and effective at a dose of 12 mCi/kg of [^{131}I]MIBG. A phase I study by the NANT (New Approaches to Neuroblastoma Therapy) Consortium combining irinotecan, vincristine, and escalating doses of [^{131}I]MIBG showed that MIBG is tolerable and active (six responses in 24 evaluable patients) when given at a dose of 18 mCi/kg with standard doses of vincristine and irinotecan [55]. The COG pilot study ANBL09P1 is testing the administration of 18 mCi/kg [^{131}I]MIBG as the last cycle of induction prior to first stem-cell infusion in newly diagnosed patients, followed by BuMel conditioning prior to second autologous HCT.

Allogeneic transplantation

Allogeneic HCT has been proposed as an alternative to autologous HCT with the hope that the allogeneic cells will provide a further "graft-versus-neuroblastoma" effect, and also decrease any risk of tumor cell reinfusion. To date, lack of evidence of immunologic benefit, coupled with the problems of frequent lack of an human leukocyte antigen (HLA)-compatible sibling donor and the significantly higher toxic death rates, have discouraged extensive use of allogeneic transplantation. Non-relapse death rates were generally higher than those reported for autologous transplants, in the range 15–30%. A CCG study compared two concomitant groups of patients in a pilot study who received the same induction and conditioning regimen; 36 patients went on to receive an autologous purged bone marrow transplant (BMT), and 20 similar patients with HLA-compatible sibling donors received allogeneic BMT [56]. There was no significant difference in relapse rate but there was an apparently higher risk of toxicity associated with the allogeneic group; the estimated PFS was 25% for the allogeneic group versus 49% for the autologous group ($p = 0.051$).

Ladenstein et al. [57] performed a case–control study using the EBMT Solid Tumor Registry to investigate the potential advantage of allogeneic BMT in high-risk neuroblastoma patients without prior disease progression. Seventeen allogeneic and 34 autologous BMT cases were studied, and PFS was not significantly different: 35% for autologous and 41% for allogeneic BMT at 2 years, respectively.

Currently, autologous HCT continues to be the preferred method of support for high-dose therapy, and allogeneic HCT is reserved for specific clinical trials testing immunomodulatory effects. One example is the use of allogeneic HCT for patients relapsing after autologous HCT (NCT01156350). Similarly, the use of escalating doses of natural killer (NK) cell infusions from allogeneic or haploidentical donors is also currently under investigation in phase I trials (NCT01287104, NCT01576692) [58].

Hematopoietic cell source and purging

Bone marrow involvement by neuroblastoma is extremely common in children with metastatic disease, present by light microscopy in 60–80% of children with INSS Stage 4 disease at diagnosis. Detection of tumor by immunocytology using a mixture of monoclonal antibodies reactive at the cell surface has been shown to detect tumor reliably with a sensitivity that may vary from 1/10^4 to 1/10^6 nucleated bone marrow cells, depending on the method used [59–61]. Circulating tumor cells in blood are detectable by immunocytology at diagnosis in up to 50% of children with Stage 4 neuroblastoma. Furthermore, tumor cell concentration in bone marrow has been associated with poorer outcomes. The occasional reports of miliary lung relapse after autologous HCT, the site one would expect to be involved after intravenous infusion of tumor cells, supports the importance of tumor-free hematopoietic cell grafts [62].

Therefore, purging of hematopoietic cells has been studied, either by positive selection of CD34$^+$ cells or by immunomagnetic purging with antineuroblastoma tumor antibodies. Although earlier reports suggested that purging of bone marrow may be important, the widespread use of peripheral blood as the stem-cell source may have different implications. Immunomagnetic purging of neuroblastoma cells was evaluated in a group-wide phase III COG study (A3973), and did not confer a significant advantage in 2-year EFS or OS in the context of dose-intensive chemoradiotherapy and biologic therapy in first response [63]. Although all peripheral blood stem cells (PBSCs) infused were shown to be tumor free by immunocytology, more sensitive detection methods using quantitative reverse transcription polymerase chain reaction (qRT-PCR) had shown that tumor cells may still be present in a significant number of PBSC grafts, and purging may not have removed all neuroblastoma cells [64]. There is still uncertainty whether the lack of benefit of purging is due to reinfusion of microscopic amounts of tumor in the PBSC or to the fact that other areas of resistant microscopic residual disease in the patient have not been eliminated.

Minimal residual disease

Despite improvements in EFS using high-dose therapy, the relapse rate, even for patients transplanted in CR, remains high [2,19]. Immediately after HCT, when disease is likely to be minimal, provides the ideal window of time to eradicate resistant clones that are still present using novel therapies not dependent upon standard cytotoxic mechanisms. It has been demonstrated that children undergoing HCT who have residual disease by [^{123}I]MIBG scan (a Curie score of >0) have a significantly worse EFS after HCT [65]. Minimal residual disease in bone marrow by qRT-PCR after HCT also is predictive of higher risk of relapse [66]. Even when residual disease is undetectable by these sensitive tests, relapse after myeloablative therapy and HCT is frequent, especially in bones and bone marrow.

In vitro, both all-*trans*-retinoic acid and isotretinoin (13-*cis*-retinoic acid) cause decreased proliferation and differentiation in neuroblastoma cell lines, including some established from refractory tumors [67,68]. After some pilot studies, a phase III randomized trial of children with high-risk neuroblastoma completing consolidation chemotherapy or autologous HCT showed that the 3-year EFS was significantly better for the patients randomized to isotretinoin (Figure 63.3a) [41]. Long-term follow-up showed improvement in OS. The apparently contradictory report from the ENSG showed no advantage for using isotretinoin to treat MRD after myeloablative therapy [69]; this is likely attributable to the low isotretinoin dose employed in that study.

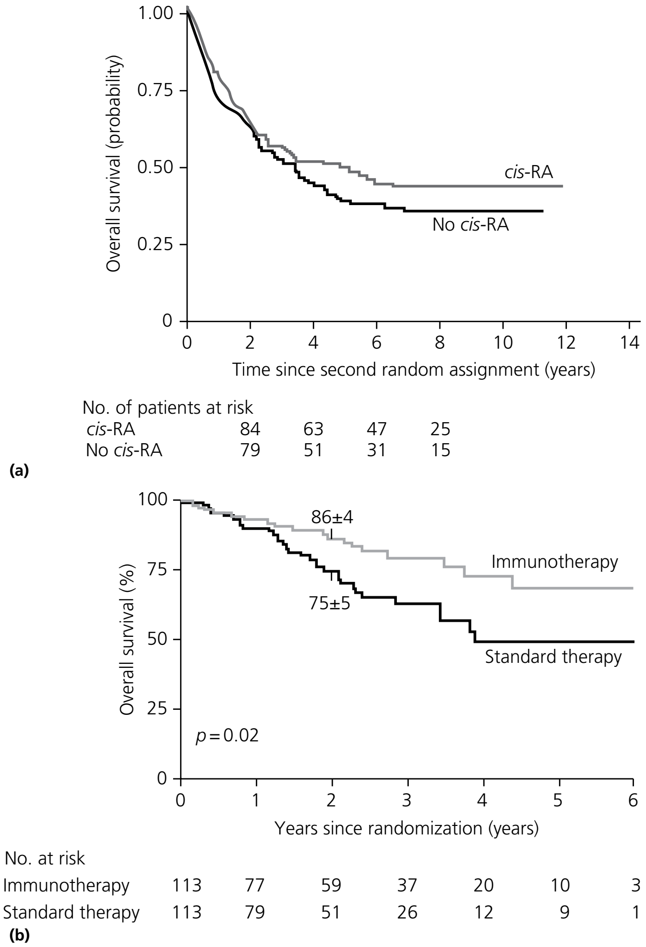

Figure 63.3 Treatment of minimal residual disease with isotretinoin and immunotherapy. (a) Use of isotretinoin in the treatment of minimal residual disease after HCT for high-risk neuroblastoma. Follow up began at the time of randomization, 34 weeks after diagnosis, with no significant difference in OS 5-year overall survival (p = 0.19). Source: Matthay et al. 2009 [41]. Reproduced with permission of the American Society of Clinical Oncology. (b) Use of immunotherapy (Ch14.18, IL-2, and GM-CSF) improves EFS after HCT for high-risk neuroblastoma. The 2-year estimate for overall survival was 86 ± 4% in the immunotherapy group and 75 ± 5% in the standard-therapy group (p = 0.02). Source: Yu et al. 2010 [76]. Reproduced with permission of the Massachusetts Medical Society.

Other retinoids such as fenretinide are currently under investigation for MRD. In contrast to isotretinoin, fenretinide does not induce maturational changes, but is cytotoxic and induces both apoptosis and necrosis [70]. In a phase II study, 62 patients with recurrent or refractory neuroblastoma were treated with 7 days of fenretinide 2475 mg/m^2/day divided three times daily every 21 days for a maximum of 30 courses [71]. Prolonged stable disease (SD) was seen in 14/59 evaluable patients, but this did not meet the study criteria for efficacy. Pharmacokinetic studies suggest that variably low bioavailability may have contributed to the modest effect. A study by the NANT Consortium investigated a new liquid fenretinide preparation in lipid to enhance absorption (fenretinide/LYM-X-SORB), and was able to demonstrate increased plasma levels at much lower doses, with four complete responses and six more with stable disease in 29 patients treated with 4–26 courses of therapy [72].

Another approach is the use of antibody-targeted therapy. Antibody therapy in relapsed neuroblastoma using monoclonal anti-GD2 antibodies has provided promising responses [73–75]. A randomized prospective trial assigned 226 patients in remission after high-dose therapy and HCT to receive isotretinoin alone, or the retinoid plus chimeric anti-GD2 antibody (Ch14.18) with granulocyte–macrophage colony-stimulating factor (GM-CSF) and interleukin-2 (IL-2). Toxicities were significant but manageable. Both 2-year EFS and OS were superior in the immunotherapy group (66% vs. 46% and 86% vs. 75%; Figure 63.3b) [76]. Further improvements are being tested using a fusion protein of the humanized form of the antibody, Hu14.18, and IL-2 [77].

Another avenue of study includes the inhibition of angiogenesis. Testing in animal models suggests responsiveness to angiogenic inhibitors, particularly in minimal disease states. Much investigation has focused upon new and novel antiangiogenic small molecules and antibodies, with promising results in cell lines, in vitro models, and xenografts. Vascular endothelial growth factor (VEGF) inhibitors alone and in combination with chemotherapeutics showed promise [78]. Early studies of multitargeted tyrosine kinase inhibitors to VEGF, platelet-derived growth factor (PDGF) and fibroblast growth factor (FGF) are also under way [79].

Other studies have focused on harnessing the patient's immune system to target residual tumor cells [80]. The use of new immunomodulatory agents such as lenalidomide in combination with anti-GD2 antibody is under investigation by the NANT Consortium (N11-04). Cellular therapy for neuroblastoma and genetically engineered cellular vaccines to generate immune responses are also under investigation, including cytotoxic T-lymphocytes (CTLs) specifically engineered to recognize neuroblastoma proteins in the context of MHC I. Invariant NKT cells are a subtype of lymphocyte capable of enhancing antitumor activity through rapid and copious inflammatory cytokine release at the site of tumor; however, clinical trials attempting to enhance NKT function in neuroblastoma patients have not yet been performed. NK cells in particular may play a vital role in tumor surveillance post-transplant. Favorable combinations of NK cell killer immunoglobulin-like receptor (KIR) and HLA genotypes have been correlated with superior outcomes post-transplant [81].

Acute and late complications of HCT in neuroblastoma

The complications of high-dose therapy and HCT for neuroblastoma are similar to those of other high-dose regimens, and vary with the particular conditioning regimen (see Section 7). The most common acute complications with most preparative regimens for neuroblastoma include the toxic effects of the high-dose therapy, with frequent mucositis, sinusoidal obstruction syndrome (SOS), fever, and infection. Potentially fatal complications include gastrointestinal hemorrhage, pneumonitis and acute respiratory distress syndrome (ARDS), severe SOS with renal failure, or, rarely, intracranial hemorrhage or cardiac failure. Toxic death rates generally have ranged from 5 to 20% on autologous HCT protocols (Table 63.3). With increasing expertise, more rapid engraftment with peripheral blood hematopoietic cells, and the removal of TBI from most regimens, the acute toxic death rate appears to be decreasing to less than 5% [29,47,82].

With more patients surviving, later complications of high-dose therapy are becoming noticeable. One common complication particular to neuroblastoma is the frequent occurrence of significant hearing loss post-transplantation, seen in 10–20% of children. These patients receive large doses of platinum compounds during induction chemotherapy and again with many of the preparative regimens. They also are exposed to other ototoxins, including aminoglycoside antibiotics, diuretics, and noise exposure, all of which may exacerbate the effects of platinum compounds [83]. Newer studies are investigating the role of gene polymorphisms that may predispose certain patients to more severe platinum-induced ototoxicity; this may lead to the development of strategies to reduce hearing loss in some patients [84]. Another late effect seen because of the young age of the children with neuroblastoma is abnormal dental development and growth delay [85].

Earlier studies of transplant in neuroblastoma reported a low incidence of second malignancies, with only one patient in 129 in the CCG study [2] and two of 509 patient in the EBMT Registry report [44]. However, secondary malignancies may increase in frequency, as the high doses of alkylators and etoposide in both the induction and conditioning regimens have been shown to result in secondary leukemia [86]. Some children have now been reported to develop secondary leukemia after radiopharmaceutical therapy for neuroblastoma [52,87]. In addition, some unusual second malignancies have been reported after transplantation for neuroblastoma, such as renal cell carcinoma [88].

Conclusion

The use of myeloablative chemotherapy has been shown to improve EFS and OS for children with advanced neuroblastoma over the last three decades. It is vital now to increase the number of patients achieving response during induction with better chemotherapy and targeted agents, as approximately 15–20% of patients will progress early and become ineligible for HCT. The tumor reduction during the transplant conditioning may be further improved by using radio-targeted therapy, and integrating new non-cross-resistant agents into current protocols. It has also been shown that therapy for MRD post-transplantation is a critical component of the improvement in outcome for neuroblastoma. New targeted approaches to MRD deserve study, including inhibitors of key genetic pathways, differentiating agents, antiangiogenic agents, and immunologic approaches. Lastly, it is critical to refine the therapy of these children to reduce the serious late complications of treatment, and to study health-related quality of life in the survivors.

CHAPTER 64

Hematopoietic Cell Transplantation for Other Pediatric Solid Tumors

Masanori Hayashi, David M. Loeb and Allen R. Chen
Johns Hopkins University School of Medicine, Baltimore, MD, USA

Introduction

Chemosensitivity

As a result of ongoing improvements in diagnosis, multimodal therapy, and supportive care, the treatment outcome of children with cancer has steadily improved since 1960. For instance, the 5-year survival of children with Wilms tumor has risen from under 45% to over 90%, for rhabdomyosarcoma from under 20% to 70%, and for Ewing sarcoma from 10% to 60% (reviewed in [1]). Improvements were possible, in part because the most frequent pediatric solid tumors (neuroblastoma, Wilms tumor, rhabdomyosarcoma, retinoblastoma, germ cell tumor, osteosarcoma, and Ewing sarcoma) are all chemosensitive.

However, subsets of patients have been defined who face a poor prognosis despite having initially chemoresponsive disease. Examples include patients over 18 months of age with metastatic neuroblastoma (see Chapter 63), and patients with metastatic Ewing sarcoma (see below). For such patients treated conventionally, the prognosis for disease-free survival (DFS) 3 years from diagnosis remains less than 20%.

In addition, the prognosis for recurrent or refractory pediatric solid tumors is dismal, and few patients have experienced prolonged survival. Most pediatric solid tumor patients are treated with intensive chemotherapy, and most recurrences occur during treatment or within 1 year of its completion. Rapid recurrence indicates the presence of tumor cells resistant to the chemotherapeutic agents used. Tumor cells often manifest substantial cross-resistance to multiple antineoplastic agents, including drugs to which the cells were never exposed.

Dose–response

For radiation and most classes of chemotherapeutics, including alkylators, anthracyclines, vinca alkaloids, and antimetabolites, there is a steep linear relationship between drug concentration and the log tumor cell kill assessed by in vitro colony formation and limiting dilution assays [2]. This steep log–linear dose–response relationship translates into important effects of chemotherapy dose on tumor response and survival in experimental tumor-bearing animals. In studies of the treatment of animals with osteosarcoma and mammary adenocarcinoma, sharp reductions in complete response (CR) and partial response (PR) rates accompany small (~15%) reductions in the dose of single agents of all classes, including antimetabolites (5-fluorouracil and 6-mercaptopurine), anthracyclines (doxorubicin and daunorubicin), antimicrotubule agents (vincristine), and alkylators [melphalan and cyclophosphamide (CY)]. In this system, the only curative single agent is CY, given at the dose that causes lethal toxicity in 30% of animals (LD30). Various combinations of chemotherapy can produce cures at <LD10, but even so, modest (~33%) dose reductions eliminate cures [3]. Of great relevance to pediatric oncology is a rhabdomyosarcoma xenograft model demonstrating a strong effect of the dose of melphalan on the tumor response of six primary tumor cell lines, including one from a CY-resistant tumor. Importantly, melphalan at adequate doses is much more active than the standard chemotherapy combination for rhabdomyosarcoma, vincristine, actinomycin D, CY, and doxorubicin [4].

Modeling of experimental data indicates that the likelihood of cure correlates best with dose intensity, whereas the duration of PR correlates best with the total dose of chemotherapy. The maximum cumulative dose of alkylators and anthracyclines that can be administrated safely does not increase when the dose intensity is reduced. It is therefore advantageous to maximize dose intensity; the maximum dose intensity is achieved by giving a single, very large course of drug [5].

Dose limiting myelotoxicity

For agents such as melphalan, carmustine, and carboplatin, whose major dose limiting toxicity is myelosuppression, hematopoietic cell transplantation (HCT) may permit 3–10-fold dose escalation. Given a steep dose–response relationship, this approach may translate into several log more cell kill and improved durability of response.

Indications and outcomes

Ewing sarcoma family of tumors

Epidemiology and etiology

The Ewing Sarcoma Family of Tumors (ESFT) encompasses Ewing sarcoma, primitive neuroectodermal tumor (PNET), Askin tumor, and peripheral neuroepithelioma, diseases previously considered distinct. The recognition that these tumors are all characterized by a reciprocal chromosomal translocation involving a gene on chromosome 22 known as EWS with a fusion partner that is an *ets* family member transcription factor has resulted in their reclassification as a distinct, molecularly defined tumor type. Although clearly a single group of tumors, there is a spectrum of differentiation

within this group: the typical undifferentiated Ewing sarcoma lies at one end of the spectrum and PNET with neural differentiation lies at the other. The ability to characterize these tumors molecularly and the growing reliance upon evaluation of chromosomal abnormalities as the definitive means of establishing a diagnosis are emblematic of the era of molecular oncology.

ESFT are the second most common type of malignant bone tumor, behind osteosarcoma. These tumors account for 2% of childhood cancers, according to data from the Surveillance, Epidemiology and End Results (SEER) section of the National Cancer Institute. SEER data, however, are stratified for age, and therefore make epidemiologic understanding of these tumors that affect both adolescents and young adults difficult. Moreover, SEER data do not break down adult sarcoma incidence by histology, making a true understanding of the epidemiology of ESFT in the United States impossible. A review of the M.D. Anderson Cancer Center tumor registry evaluated the epidemiology of sarcomas in the adolescent and young adult (AYA) population without restrictions based on age or histologic subtype [6]. In this study, ESFT accounted for 25% of the bone sarcomas in the AYA population, whereas osteosarcoma accounted for 57%. These data allow an estimation of new cases in the United States every year of 390 ESFT of bone and 170 of soft tissue.

ESFT incidence peaks in the second decade of life, and is predominantly a disease of the AYA population. About 64% of cases occur in the second decade of life, compared with 27% in the first decade and only 9% in the third [7]. The M.D. Anderson data corroborate that finding, as chondrosarcoma was the second most frequent bone sarcoma histology in the population as a whole (28% of cases), but ESFT was more frequent in the AYA group. Interestingly, ESFT is overwhelmingly a disease of White children. In New York, ESFT represents 22% of primary bone cancers in Whites, but only 7% in Blacks [8].

ESFT are not commonly associated with other congenital diseases, or with skeletal abnormalities or other cancers. No constitutional chromosomal abnormalities have been reported in patients with ESFT, and the concordance rate in siblings is very low. ESFT are rarely reported as second malignant neoplasms in patients previously treated for cancer.

Molecular and cellular biology

These tumors are defined molecularly by the presence of a reciprocal translocation t(11;22)(q24;q12) that fuses a gene known as EWS with the ETS family transcription factor FLI1 and is found in 85% of such tumors [9]. Alternative reciprocal translocations, such as t(21;22)(q22;q12), t(7;22)(p22;q12), t(17;22)(q12;q12), and t(2;22)(q33;q12), all of which result in a fusion between EWS and an *ets* family transcription factor, have been reported in the remaining 15% [10]. Several studies have suggested that EWS–FLI1 is oncogenic, and is sufficient to initiate and maintain the transformed phenotype [11]. In fact, inhibition of the fusion gene in cell lines inhibits growth in vitro [12]. In addition to the defining translocation, numerous other cytogenetic abnormalities have been described in ESFT, and Sandberg and Bridge provided a comprehensive overview [10].

Controversy still surrounds the most basic cellular biological question related to ESFT, namely the cell of origin. There is cytologic and ultrastructural evidence of neural maturation in the more differentiated ESFT tumors [13] that were formerly classified as PNET. An attempt to establish the histogenesis of ESFT cell lines by analysis of intermediate filament expression, however, suggested an epithelial phenotype, on the basis of expression of cytokeratins 8 and 18 [14]. More recently, DNA microarrays have been employed to attempt to address this question. Gene expression profiling experiments have shown that these tumors are related to both neuronal and endothelial lineages [15]. Interestingly, expression of EWS–FLI1 in human embryonic kidney cells is insufficient to induce the entire ESFT gene expression profile, suggesting that the cell being tested impacts the process of differentiation. In contrast, Riggi et al. demonstrated that forced expression of EWS–FLI1 in bone marrow-derived mesenchymal progenitor cells induces the formation of tumor cells with all of the essential hallmarks of ESFT [16]. Thus, support can be found in the literature for neuronal, epithelial, endothelial, or mesenchymal origin of these tumors. Future work will be required to clarify the histogenesis of ESFT.

Clinical description

A detailed description of the clinical presentation of ESFT can be found elsewhere [1]. In brief, pain and swelling are the most common presenting symptoms of ESFT, occurring in 84 and 63% of patients, respectively. These symptoms are often longstanding, with a median delay between onset of symptoms and diagnosis in excess of 6 months. Although tumors can arise in any bone in the body and in soft tissue, these tumors show a predilection for the lower extremity (46%) and pelvis (20%). ESFT is a very aggressive malignancy, with 25% of patients presenting with overt metastases. Of these, half have metastases to the lungs, one-quarter to other bones, and one-fifth to bone marrow. Metastases to other sites are rare, except in late-stage disease.

Non-transplant approaches

For these tumors, the primary adverse risk factor is the presence of metastatic disease. A more recently recognized prognostic factor is histologic response to chemotherapy. Data from the Rizzoli Institute showed 95% DFS for patients with localized disease and complete tumor necrosis, compared with 34% for patients with macroscopic viable tumor at the time of definitive surgery. Pelvic primary disease or a large tumor size (>8 cm in maximal diameter or >100 mL in volume) historically carried a poor prognosis for survival. Through intensification by the addition of ifosfamide and etoposide, EFS has improved from 54 to 69% for patients with localized disease and eliminated pelvic primary location and large tumor size as prognostic factors [17]. Unfortunately, even with this addition, which has now become standard of care, the 22% EFS of patients with metastatic disease has not improved. The recently published Children's Oncology Group (COG) study tested increasing dose intensity by randomizing patients to receive this same treatment regimen of alternating cycles of vincristine–doxorubicin–cyclophosphamide and ifosfamide–etoposide with cycles given at 2-week intervals versus the standard 3-week intervals. The 5-year EFS was 65% for patients with localized disease treated at 3-week intervals, but 73% for patients treated with the time-compressed regimen [18], lending further support to the importance of dose and time intensity for the cure of pediatric solid tumors.

In addition to systemic chemotherapy, adequate local control is essential to eradicate the disease. Local control measures include radiation therapy and surgery. The relative efficacy of radiotherapy compared with surgery remains controversial. Studies utilizing dose-intensive chemotherapy showed little difference in survival between patients treated with surgery and patients treated with radiation [19], with respect to both local recurrence and overall survival (OS). In a single-institution study of 76 patients with localized disease, the local failure rate was identical in the patients treated with radiation, surgery, or both [20]. Interestingly, in a multivariate analysis, only the use of chemotherapy was a prognostic factor for local control (the 10-year local control rate for patients treated with chemotherapy was 83.7%, compared with 51.1% for patients who did not receive chemotherapy), supporting the concept that systemic treatment contributes to local control.

Hematopoietic cell transplantation

Patients with high-risk ESFT, including patients with metastatic or recurrent disease, have a very poor prognosis. Dose-intensive chemotherapy has not improved the outcome for patients with metastatic disease, and patients with recurrent disease are not cured with standard chemotherapy. For these patient populations, HCT has been investigated as a way to improve outcomes. One of the earliest and largest reports of high-dose therapy investigated the use of total body irradiation (TBI) with autologous peripheral blood progenitor cell (PBPC) support as consolidation therapy for high-risk ESFT patients. Over a 5-year period, 91 patients were treated on three successive chemotherapy protocols at the National Institutes of Health (NIH), and remissions were consolidated in 65 of the patients with 8 Gy of TBI [21]. Nineteen patients were not given TBI, because they failed to achieve remission or relapsed prior to treatment, and seven refused. Twenty of the 65 treated patients became long-term survivors (31%), a higher rate than expected with chemotherapy alone in this group of patients, and superior to a group of contemporary patients treated without high-dose therapy. However, only patients who did not progress after chemotherapy were eligible for HCT, so OS for the total patient population was only 22%, no better than results with chemotherapy alone. Subsequent studies confirmed that HCT appears to offer a survival advantage to select patient groups, such as those with chemosensitive metastases limited to the lungs (Figure 64.1) [22].

More current results from European Bone Marrow Transplant Registry (EBMTR) data combined with data from the Pediatric Registry for Stem Cell Transplantations (PRST), Asia Pacific Blood and Marrow Transplantation (APBMT) and Meta European Intergroup Cooperative Ewing Sarcoma Study (MetaEICESS) suggest several improvements. Although the data are from non-randomized patients, a 5-year OS of 44% was reported for patients treated with a busulfan-containing regimen, compared with 23% for patients treated without this drug [23].

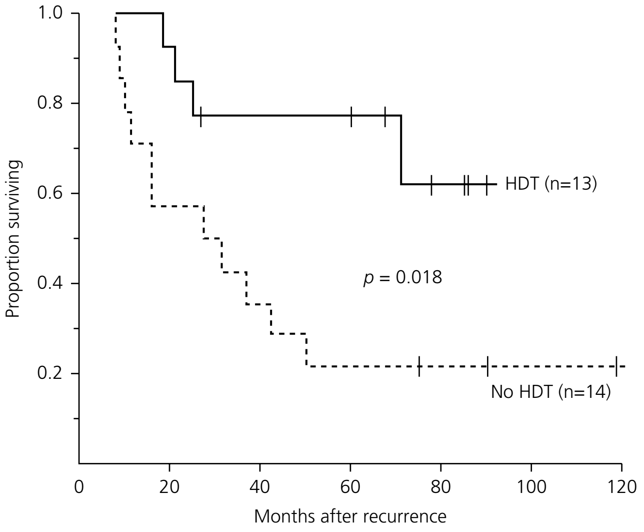

Figure 64.1 Survival from time of first recurrence for patients with recurrent ESFT who responded to salvage induction chemotherapy, by use of high-dose therapy (HDT). Source: Barker et al. 2005 [22].

A follow-up study published from the previously mentioned EBMTR data, included 87 patients, mostly (n = 69) from the EBMTR, who had a molecularly confirmed diagnosis of ESFT, and the outcome was assessed based on transplant regimen used. Other than a higher incidence of relapse in the reduced-intensity conditioning group, there were no differences in OS rates, failing to address this question [24].

All of the studies summarized above share the same weakness – none was prospective and randomized. This limits the confidence with which HCT can be recommended as "standard of care" for ESFT patients. An ongoing study, Euro-Ewing 99, was designed to address this deficiency. In this study, patients are assigned to one of three risk groups, based on the presence or absence of metastases, the size of the primary tumor, and response to neoadjuvant therapy. Patients in the lowest risk group are treated with 14 cycles of chemotherapy. Patients judged to have intermediate-risk disease (PR, rather than CR to neoadjuvant therapy, a tumor >200 mL, or pulmonary metastases) are randomized to consolidation with chemotherapy versus high-dose therapy with busulfan and melphalan. The patients with the highest risk (extrapulmonary metastases) are treated with either of two different preparative regimens for their HCT according to physician discretion, although the recommended treatment is a busulfan–melphalan-based regimen. For the highest risk patients, the results have been published and showed a 3-year event-free survival (EFS) of 27% and an OS of 34% [25]. Although several favorable prognostic factors were identified in this otherwise very high-risk group (such as isolated bone marrow metastasis, smaller tumor size, and fewer sites of metastasis), the utility of HCT in this population remains unclear. Results from the remaining arms of the study are expected to resolve some of the controversies surrounding the utility of HCT for patients with ESFT, especially patients with intermediate-risk disease.

Rhabdomyosarcoma

Epidemiology and etiology

Rhabdomyosarcoma is the most common soft tissue sarcoma of childhood, accounting for 5–8% of childhood cancer [7]. About 250 new cases of rhabdomyosarcoma are diagnosed in the United States annually, slightly more frequently in boys than in girls. Little is known about the etiology of rhabdomyosarcoma. These tumors sometimes arise as second malignant neoplasms in patients previously treated with ionizing radiation, but radiation exposure accounts for a very small minority of cases.

Molecular and cellular biology

There are two major histologic variants of rhabdomyosarcoma: embryonal and alveolar. Embryonal rhabdomyosarcoma, named for its resemblance to immature skeletal muscle, has been subdivided into solid and botryoid variants. Embryonal histology accounts for 57% of cases of rhabdomyosarcoma and usually affects children between 3 and 12 years of age. Alveolar histology, named for its resemblance to normal lung parenchyma, accounts for 19% of cases of rhabdomyosarcoma, and usually strikes patients between 6 and 21 years old. Embryonal rhabdomyosarcoma carries a more favorable prognosis than alveolar.

As in ESFT, recurrent translocations have been identified in rhabdomyosarcoma, although only in the alveolar subtype. In 55%

of cases, a translocation between chromosomes 2 and 13, t(2;13)(q35;q14), is seen, and in 22% of cases a similar translocation involving chromosome 1, t(1;13)(p36;q14), is identified [26]. These translocations involve related transcription factor genes, PAX3 and PAX7, respectively. The PAX3–FKHR translocation appears to carry a poorer prognosis than PAX7–FKHR. In each case, the DNA-binding domain of the PAX gene is fused to the transactivation domain of the FKHR gene. Disruption of PAX genes leads to abnormal muscle development [27], suggesting a direct etiologic relationship between the translocation and the development of malignancy. Moreover, ectopic expression of these chimeric genes can transform cells. It is probably the translocation oncogene, rather than histology, that dictates the course of disease. In fact, tumors histologically classified as alveolar rhabdomyosarcoma but which are fusion gene negative behave similarly to embryonal rhabdomyosarcoma, both clinically and molecularly [28], and based on this observation, molecular staging systems have recently been proposed [29].

Clinical description

Signs and symptoms present at diagnosis depend on the site of the primary tumor, the involvement of surrounding normal organs, and the presence of distant metastases. Typically, patients present with an asymptomatic mass, although involvement of cortical bone may cause pain, and genitourinary disease may cause hematuria or urinary retention. Different subtypes of rhabdomyosarcoma arise in different sites. Embryonal rhabdomyosarcoma typically arises in the head and neck region or the genitourinary tract, while alveolar rhabdomyosarcoma tends to arise in the extremities and the trunk [1]. Head and neck sites, including orbit and parameningeal primaries, account for 40% of cases, trunk and extremity sites 25–30% of cases, and genitourinary sites 20% of cases. The most common sites of metastasis are the lungs, lymph nodes, cortical bone, and bone marrow.

Non-transplant approaches

Rhabdomyosarcoma is treated with multimodality therapy, including chemotherapy, radiation therapy, and surgery. Surgery alone is insufficient to cure even localized disease. In the era before the development of effective systemic chemotherapy, OS for patients with localized disease was 25% or less, but with current multimodality therapy, failure-free survival rates for patients with localized disease are as high as 90% [30].

The most important predictor of treatment failure is the clinical group identified in early Intergroup Rhabdomyosarcoma Study Group (IRSG) studies (Table 64.1). In addition to classification by clinical group, rhabdomyosarcoma is also staged using a specific TNM staging system [30] that takes into account not only tumor size, lymph node status, and distant metastases, but also incorporates information regarding the site of the primary tumor, reflecting prognostic differences between favorable and unfavorable anatomic locations. Patients are then classified as high, intermediate, or low risk based on clinical group and stage, and treatment is based on this assessment of risk. Although inclusion of molecular information seems to be promising, fusion gene status has not yet been incorporated into formal staging systems [29].

Table 64.1 Clinical group definitions for rhabdomyosarcoma patients

Group	Definition
I	Localized disease completely resected
IIa	Gross total resection with microscopic residual disease
IIb	Regionally involved lymph nodes, completely resected with the primary
IIc	Regional disease with involved nodes, totally resected with either microscopic residual disease or histologic evidence of involvement of the most distant lymph node in the dissection
III	Incomplete resection
IV	Distant metastases

The principles of non-transplant therapy for rhabdomyosarcoma, as established by the IRSG clinical trials, include local control (consisting of surgery, radiation therapy, or both) and systemic therapy to address either gross or microscopic metastatic disease. Primary surgical resection is indicated, unless the tumor is deemed unresectable. In this case, radiation therapy is employed, and can provide definitive local control for patients with unresectable rhabdomyosarcoma [31]. The specifics of adjuvant systemic chemotherapy vary depending on risk stratification. In general, the chemotherapy used for low-risk patients is based on a vincristine–dactinomycin–cyclophosphamide backbone, while intermediate- or high-risk patients utilize the same backbone with a significantly higher dose of cyclophosphamide and addition of other active agents such as irinotecan, ifosfamide, and etoposide. Unlike osteosarcoma or Ewing sarcoma family tumors, patients with rhabdomyosarcoma undergo surgical resection prior to the institution of systemic therapy, as reflected in the staging system, which takes into account the extent of resection. Upon recovery from surgery, patients are treated with chemotherapy with or without radiation, which is usually delivered relatively early in the treatment regimen.

Hematopoietic cell transplantation

The role of high-dose therapy and HCT in high-risk rhabdomyosarcoma is not established. Several retrospective analyses have been reported. Between 1982 and 1994, the EBMTR received reports of 98 transplants performed in children and young adults with relapse or progression of initially localized rhabdomyosarcoma. The proportion surviving disease free is approximately 20%, and median survival remains short, only 8.3 months from HCT [32]. The German–Austrian Pediatric BMT Group in 1997 published the results of 36 transplants performed for metastatic or recurrent rhabdomyosarcoma between 1986 and 1994. Thirty-four of the 36 patients received high-dose melphalan-based regimens, usually augmented with etoposide and carboplatin. The estimated EFS at 2 years after HCT was 36 ± 7% [33]. This rate is better than expected, but the small number of patients and possible effects of selection bias preclude conclusions about the efficacy of HCT for rhabdomyosarcoma.

The European Collaborative MMT4-91 trial was the first prospective trial to evaluate the efficacy of HCT as consolidation therapy in first remission for patients who presented with metastatic rhabdomyosarcoma. This study resulted from the amendment of MMT4-89 for patients with newly diagnosed metastatic rhabdomyosarcoma, so that institutions could chose to substitute HCT with high-dose melphalan for the fourth and final 9-week cycle of chemotherapy in patients who had achieved CR before the third cycle of therapy. Hence there was a nearly contemporaneous control population of patients either enrolled on MMT4-89 or enrolled on MMT4-91 at centers not participating in HCT. Fifty-three patients in CR after six courses (two cycles) of chemotherapy were treated with high-dose melphalan, either alone or in combination with other agents such as carboplatin, etoposide, thioTEPA, and/or busulfan. Outcomes were compared with those for 44 patients who were also in CR after six identical cycles of chemotherapy but went on to receive further conventional dose chemotherapy rather than HCT. Although patients were not randomized to HCT or conventional therapy, decisions to administer HCT consolidation were made at the center level, reducing the potential for selection bias. Unfortunately, the patient population treated with HCT ($n = 53$) in fact had poorer prognostic factors: lymph node involvement was more common (56% vs. 34%), alveolar histology was more common (44% vs. 30%), fewer patients were <10 years old (60% vs. 68%), and more patients had large tumors >5 cm in diameter (73% vs. 61%) than in the control population ($n = 44$). Despite these differences and the small sample size, the median time from the end of therapy to relapse was significantly longer for the HCT group than the conventional chemotherapy group (168 vs. 104 days, $p = 0.05$), but there was no difference in EFS or OS [34]. Single-institution protocols for high-risk rhabdomyosarcoma that incorporate HCT consolidation showed similar results, with DFS for Stage IV patients ranging from 14 to 28% at 3 years or more [35–38].

Wilms tumor

Epidemiology and etiology

Wilms tumor is the most common renal malignancy of childhood, with an annual incidence in the United States of 8.1 cases per million children under age 15 years, with a slight female predominance. Children with bilateral disease have an earlier age of onset, 23.5 months for males and 30.5 months for females, than those with unilateral disease, 36.5 for males and 42.5 months for females. This age difference for laterality was a key observation in the development of Knudson's classic two-hit model of tumorigenesis [39]. The additional variation in age of onset by gender and ethnicity suggested heterogeneity in the pathogenesis of Wilms tumor [40].

Molecular and cellular biology

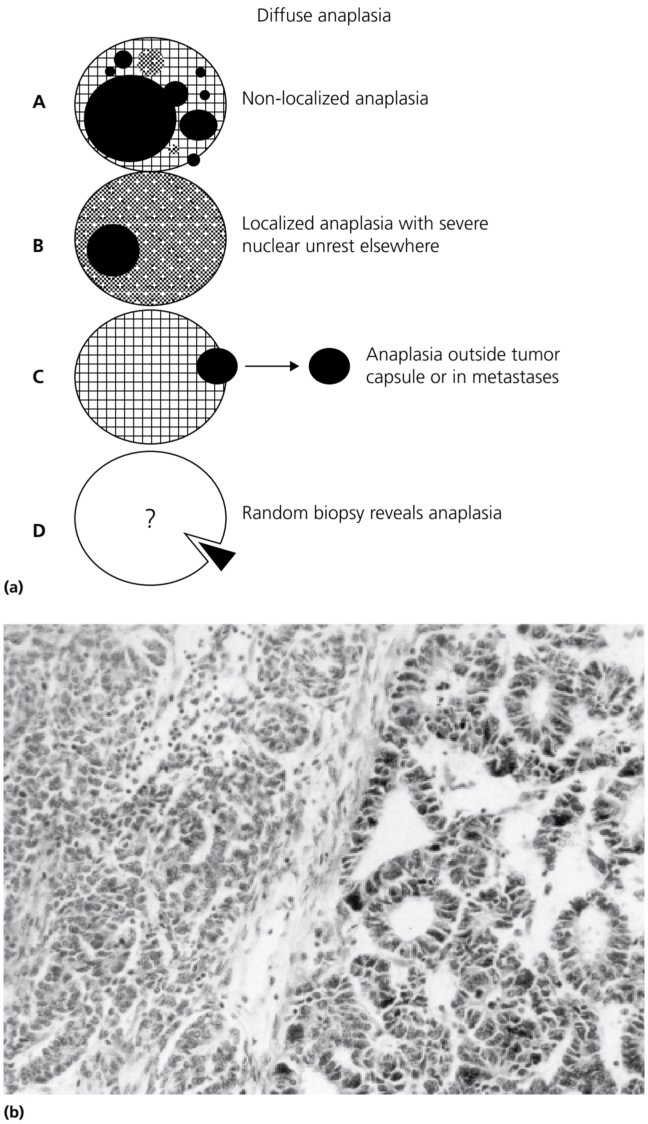
Molecular correlates of these epidemiologic observations have subsequently been identified. In most normal tissue, imprinting of the insulin-like growth factor 2 gene, IGF2, silences the maternal allele, so only the paternal allele is expressed. In a study of 36 informative Wilms tumor specimens, loss of imprinting that led to expression of the normally silent maternal allele was strongly associated with perilobular nephrogenic rest histology and a 2.2-fold increased expression of IGF2 [41]. Conversely, mutation of the Wilms Tumor 1 (*WT1*) suppressor gene is associated with earlier age at onset, stromal-predominant histology, intralobular nephrogenic rests, and poorer response to therapy [42]. Other genetic abnormalities identified in Wilms Tumor include mutation of the WTX gene and also mutations in CTNNB1 [43], which are both components of the Wnt signaling pathway. Molecular markers are increasingly being recognized as prognostic predictors, and loss of heterozygosity of 1p and 16q is associated with decreased EFS and OS in otherwise favorable histology Wilms tumor [44].

Clinical description

Children with Wilms tumor typically present with a painless abdominal mass or abdominal distention. Other findings include gross hematuria and fever. Hemorrhage into the tumor can result in a rapidly expanding abdominal mass and anemia. Compression of renal vasculature can produce hypertension. Radiographic findings can usually distinguish Wilms tumor as an intrinsic renal mass from neuroblastoma arising in the adrenal gland and displacing the kidney. Patterns of spread include local extension beyond the tumor pseudocapsule into the renal sinus, the renal vasculature, and lymphatics. The tumor can be locally aggressive, violating the renal capsule, and can disseminate through lymphatics. Hematogenous dissemination is primarily to the lungs, and less commonly to the liver.

Non-transplant approaches

Wilms tumor is the exceptional childhood solid tumor that is often curable by conventional chemotherapy when metastatic at diagnosis, and even after relapse. However, high-risk groups can be defined. The National Wilms Tumor Studies NWTS-2 and NWTS-3 accrued 2757 untreated patients aged 15 years or younger, with Stage I–IV disease. The prognosis of the 367 patients (14%) who relapsed after achieving an initial CR was analyzed in 1989. Histology was an important predictor of outcome, with unfavorable histology defined by the presence of diffuse anaplasia (Figure 64.2) [45]. In NWTS-3, 3-year survival after relapse was 42% with favorable histology versus 16% with unfavorable histology. Similar numbers of patients relapsed at <6, 6–11, and >12 months from diagnosis. Their respective 3-year survival rates were 18, 30, and 41%, respectively. Among patients with favorable histology, the 3-year survival by initial stage was Stage I 57%, II/III 36%, and IV 17%; for patients with unfavorable histology, 3-year survival was



Diffuse anaplasia

Stage I 17%, II/III 14%, and IV 7%. Among Stage II/III patients with favorable histology, those randomized to receive three-drug initial therapy had a 3-year survival from relapse of 16%, versus 42% among those initially treated with two-drug regimens. Intra-abdominal relapse was unfavorable when this field had been previously irradiated, precluding further radiation therapy to the site of relapse [46].

An analysis of the long-term survival outcome of patients relapsing on the UK Childrens' Cancer Study Group (CCSG) Wilms Tumor 1 trial, which accrued 381 patients from 1980 to 1986, confirmed the negative prognostic importance of unfavorable histology, high initial stage, and early relapse, given salvage with ifosfamide or cisplatin and etoposide [32]. Taken together, these results led to the accepted definition of a high-risk subgroup of relapsed Wilms tumor patients whose expected 3-year survival is under 20%, including those with any of the following features: unfavorable histology, relapse within 6 months of diagnosis, failure of a three-drug regimen, and involvement of sites other than lung and abdomen, or involving the abdomen after irradiation.

However, the National Wilms Tumor Study 5 (NWTS-5) treated patients who relapsed after vincristine and dactinomycin therapy without prior irradiation on a uniform regimen consisting of vincristine, doxorubicin, cyclophosphamide, and etoposide, combined with radiation to involved organs. Of 72 patients enrolled, 68 were evaluable, and the 58 patients aged 18 years and younger with unilateral disease at initial diagnosis were analyzed. Only 10 of the patients had no adverse prognostic features, 32 had one, and 16 had two. Nevertheless, the 4-year EFS was 71% and the 4-year OS was 82% [47], showing that aggressive conventional therapy can overcome adverse prognostic factors in minimally pretreated patients.

In contrast, results of the NWTS-5 study for patients who relapsed after initial therapy with vincristine, dactinomycin, and doxorubicin were less favorable. A total of 103 patients were enrolled in this stratum, and 91 were evaluable. The 60 patients with initially unilateral disease who relapsed after achieving a CR were analyzed. For these 60 patients, the 4-year EFS was 42% and the 4-year OS was 48%. Twenty-five patients had only one adverse prognostic factor, 22 had two or three, and 13 had four or more. More adverse prognostic factors, male gender, and sites of relapse other than the lungs conferred significantly poorer EFS [48]. In summary, there is room for improvement over the results of non-transplant chemotherapy in patients with high-risk relapses following three-drug initial therapy.

HCT for high-risk relapse of Wilms tumor

Limited published information is available regarding high-dose therapy for patients with high-risk relapse of Wilms tumor. The experience collected by the EBMTR has been reviewed [49]. Twenty-five patients with Wilms tumor received high-dose therapy over a 7-year period from 1984 to 1991. Twenty-one of these children had had one to four relapses, and four patients had Stage IV disease refractory to first-line therapy. Of 11 patients transplanted in CR2, 10 had one or more high-risk features as defined above. Twenty of the 25 patients received high-dose melphalan-based regimens, although seven different regimens were used. Eight of 17 children transplanted in CR became long-term disease-free survivors. Of patients with measurable disease, 5/8 achieved a CR and 1/8 achieved a PR to high-dose therapy, demonstrating the activity of these regimens in refractory Wilms tumor. However, only one of eight children with measurable disease at the time of HCT became a long-term survivor [49].

These results are sufficiently encouraging to warrant prospective evaluation, first in phase II trials to identify active regimens and then in a randomized comparison with chemotherapy for patients with high-risk disease. The French Society of Pediatric Oncology (Société Française de l'Oncologie Pédiatrique, SFOP) completed the first prospective trial of HCT for high-risk relapsed Wilms tumor [50]. From 1988 to 1994, 31 patients underwent HCT, including 29 relapsed (CR2, 16; PR2, 4; CR3, 3; PR3, 5; CR5, 1) and two Stage IV anaplastic Wilms tumor patients transplanted in CR1. All patients had at least one high-risk feature, and were heavily pretreated with five or six chemotherapy drugs before HCT. The preparatory regimen consisted of melphalan 180 mg/m^2, etoposide 1000 mg/m^2, and carboplatin, dosed to achieve an area under the curve of 20 mgmin/mL over 5 days. Radiation therapy was delivered to sites of bulky metastatic disease after recovery from HCT. Seven patients sustained renal tubular damage, one developed sinusoidal obstruction syndrome (SOS) of the liver but recovered fully, and three developed interstitial pneumonitis. Only one of nine evaluable patients failed to achieve CR after HCT. Sixteen patients relapsed at a median of 8.5 months (range 3–53 months) after HCT, and 12 patients remained in continuous CR a median of 48.5 months (range 36–96 months) after HCT. DFS was 50 ± 17% and OS was 60 ± 18% at 3 years [50]. The only statistically significant prognostic factor was the number of disease progressions before HCT: In second response, DFS was 63.1 ± 20%, compared with 22.2 ± 24% in third response or beyond. The results are better than historical results for high-risk patients with such advanced disease. However, over the same period, 15 patients in the participating centers with at least one adverse prognostic factor failed to undergo consolidation because of uncontrolled progressive disease (PD), and would need to be included in an intention-to-treat analysis to estimate the effect of HCT on survival from relapse in an unselected population.

The German Cooperative Wilms Tumor Studies confirmed these results, treating 23 patients with HCT from 1992 to 1998 because of defined high-risk criteria including relapse, progression, or incomplete response of initial Stage IV disease [12], second or subsequent relapse [9], relapse within a radiation field [4], bone or brain metastases [3], relapse <6 months after nephrectomy [3], or relapse of a tumor with unfavorable histology [1]. The preparative regimen was identical with that of the SFOP in 19 patients. One patient developed renal failure requiring dialysis for 1 month, and six developed tubular dysfunction. For the entire cohort, the EFS was 48% and OS 61%, but disease status at the time of HCT strongly predicted outcome: 11/13 patients in CR but only 3/10 patients in PR survived at a median follow-up of 58 months [51].

The most recently published large data set from the EBMTR was reported in 2008 and included 343 transplants for 305 patients during 1985–2005. OS for the patients in CR1, CR2, and SR (sensitive relapse: patients who had chemotherapy-responsive disease but never achieved a CR) were 71, 40, and 34%, respectively, and it seems that disease status does predict outcome although the optimum timing of HCT remains unclear [52]. The selection of a subgroup of patients who would benefit the most from HCT is important from not only the tumor response and disease-related mortality standpoint, but also from the standpoint of therapeutic toxicity, considering that many Wilms tumor patients have only one kidney. A meta-analysis published in 2013 identified 19 studies that included patients with relapsed or refractory Wilms tumor who received either conventional therapy or autologous HCT [53]. Although not conclusive owing to the difficulties in comparing patients treated with different upfront therapies, it appears that in very high-risk patients (defined as risk group III, which includes initial Stage IV with unfavorable histology, those who received at least four chemotherapy agents, and those with PD after first relapse and salvage therapy), there is a small survival advantage to HCT.

The NWTS-5 pediatric salvage protocol was initially designed to incorporate HCT for patients who failed to achieve a CR after two courses of salvage induction chemotherapy. However, the study was amended to eliminate HCT. Although the results of this salvage protocol are not yet mature, the St. Jude institutional experience and the results of the Children's Cancer Group pilot salvage protocols suggest that newer chemotherapy approaches have improved the outcome of patients with high-risk relapse even without HCT [54,55], and it would therefore be appropriate to launch an international trial to assess the value of HCT compared with conventional-dose chemotherapy in high-risk recurrent Wilms tumor, with the greatest benefit expected in patients in second response (Figure 64.3).

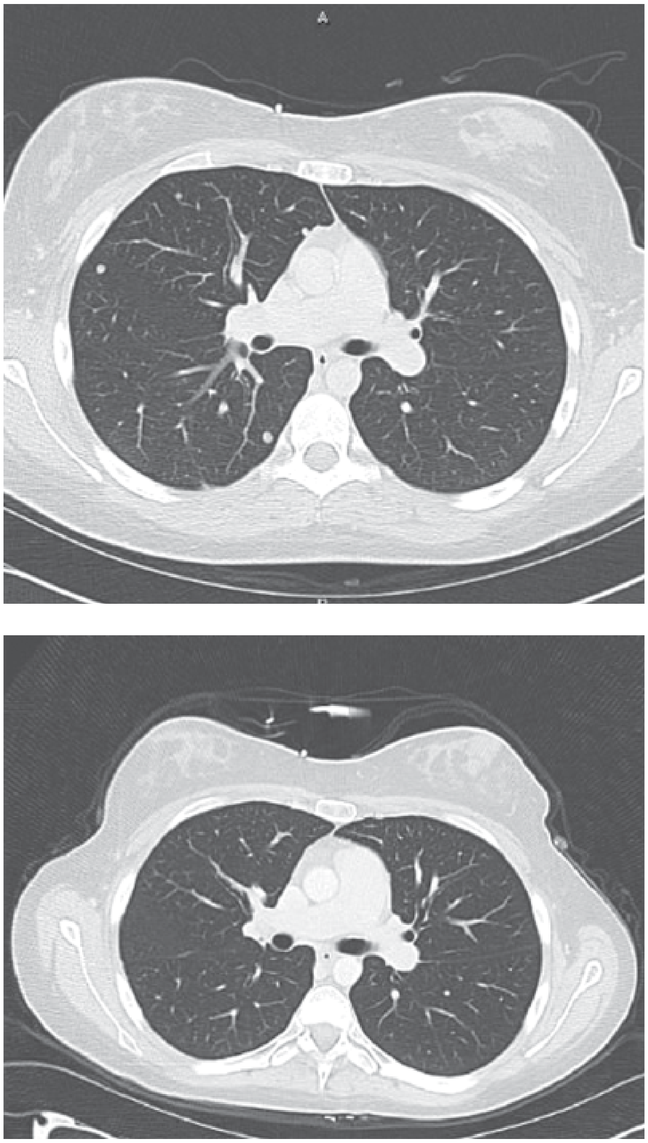

Figure 64.3 Metastatic recurrent Wilms tumor. CT scans showing first chemoresponsive relapse subsequently consolidated with autologous HCT.

HCT as consolidation for Wilms tumor

Because of the excellent curability of Wilms tumor with conventional chemotherapy, few patients have been treated with HCT for Wilms tumor in first response, all with Stage IV disease. All five patients reported by the EBMT, including two with unfavorable histology, survived disease-free at a median of 62 months (range 14–67 months) after HCT [49]; both patients with Stage IV anaplastic Wilms tumor transplanted by the SFOP died of PD [50], whereas the one similar patient treated by the German Cooperative Wilms Tumor Studies survived [51].

Osteosarcoma

Epidemiology and etiology

Osteosarcoma is the most common primary bone tumor of childhood and adolescence, and usually involves the long bones [1]. The incidence of osteosarcoma is three new cases per million per year, or 5.6 cases per million Caucasian children younger than 15 years in the United States. The peak age of onset is during the second decade of life, during the adolescent growth spurt, somewhat earlier in girls than in boys. Boys are affected more frequently than girls, a finding speculated to reflect the larger bone volume in boys compared with girls. A second incidence peak after the age of 50 years may reflect tumors induced by environmental exposures.

The only proven exogenous risk factor for the development of osteosarcoma is exposure to ionizing radiation [56]. Unlike ESFT, however, osteosarcoma has been associated with several inherited syndromes, including bilateral retinoblastoma, Li–Fraumeni syndrome, Bloom syndrome, Rothmund–Thomson syndrome, Werner syndrome, and multiple exostoses. Osteosarcoma is also associated with Paget disease. These findings have led to the identification of numerous genetic changes involved in the development of this tumor. Hence a good deal is known about the molecular biology of osteosarcoma.

Molecular and cellular biology

The recognition that patients with bilateral retinoblastoma are at increased risk of developing osteosarcoma implicates the *RB1* gene in the pathogenesis of osteosarcoma. As expected from this observation, loss of *RB1* at chromosomal locus 13q14 is a frequent finding in sporadic osteosarcoma [57]. Osteosarcoma is one of the defining tumors of Li–Fraumeni syndrome, and this has led to investigation of mutations in p53 in spontaneous osteosarcoma. Mutations in p53 occur in 40–60% of cases [58]. Both of these genes, *TP53* and *RB1*, are implicated in cell cycle regulation and proliferation. Numerous other cell cycle regulatory genes have also been implicated in this disease, including *MYC*, *CDKNA2*, *CDKN2A*, *CDKN2B*, and *MDM2* [58–60].

Chromosomal instability appears to play a key role in the molecular pathogenesis of osteosarcoma. No recurrent chromosomal translocation has been identified, but numerous loci with amplification, point mutation, or loss of heterozygosity have been reported (reviewed in [61]). This is consistent with the observation that osteosarcomas are diagnosed with increased frequency in patients with Bloom syndrome, Rothmund–Thomson syndrome, and Werner syndrome, disorders caused by germline mutations in RecQ helicases, which are involved in maintaining genomic stability [62].

In addition to these general regulatory genes, loss of function of genes implicated in bone differentiation has also been seen in osteosarcoma. Deregulated bone differentiation is commonly seen in osteosarcoma [63]. *Runx2* is a primary regulator of bone development [64] and is upstream of other regulatory genes, including OSX

[65] and TWIST [66]. The TWIST locus, 7p21, was found to be rearranged in 31 cases of osteosarcoma, deleted in 22, and amplified in nine out of a total of 68 cases examined [67]. Additionally, high Ezrin expression has been correlated with a poor outcome in osteosarcoma patients [68], a protein implicated predominantly in metastatic disease [69]. Further investigation into the molecular biology of osteogenesis will undoubtedly uncover further genes that contribute to the development of osteosarcoma.

Clinical description

The most common presenting complaint is pain [1]. Swelling and pathologic fracture are also often seen. Radiographic findings typically include a mixed osteolytic–sclerotic lesion with disorganized soft tissue calcification. At diagnosis, the disease is localized in 80% of cases, with metastases, most commonly to the lung, seen in the other 20%. Bone is the other common site of metastatic disease, with metastases rarely seen in lymph nodes. Osteosarcoma arises most frequently in the limbs (80% of cases), the femur being the most common bone. It occurs predominantly in the metaphysis of long bones, arising from the medullary cavity and invading into the epiphysis, even in the presence of a growth plate.

Non-transplant approaches

The mainstays of therapy for osteosarcoma remain surgery and chemotherapy. Until the 1970s, surgery was the only available therapy, but complete resection cured only 20% of patients. Three out of four patients died within 2 years of diagnosis, almost exclusively due to pulmonary metastases. The introduction of adjuvant chemotherapy has increased OS to almost 70% for patients with localized disease [70], although the cure rate for patients with metastatic disease remains unacceptably low. The first combination chemotherapy regimens consisted of methotrexate, doxorubicin, and cisplatin, and this combination remains the standard 40 years later. Neoadjuvant chemotherapy was introduced in the late 1970s to facilitate limb salvage surgery [71], and led to the recognition that histologic response to therapy was a strong prognostic feature. Patients with a good histologic response (>90% tumor necrosis) had 68% OS at 5 years, compared with 52% in poor responders [72]. Based on this finding, there have been several attempts to improve survival by augmenting chemotherapy for the poor responders. No such attempt has shown a statistically significant benefit [73]. The most recent COG study, AOST0331 (EURAMOS-1), randomized patients after determining histologic response to neoadjuvant chemotherapy. Poor responders were randomized to either have standard MAP (high-dose methotrexate, cisplatin, and doxorubicin) or MAP combined with ifosfamide and etoposide, and good responders were randomized to either standard MAP or MAP followed by maintenance -nterferon-α. The study closed to accrual in June 2011, and is expected to have primary end-point results around 2015. For now, the current standard therapy for osteosarcoma remains the same today as it was in 1980 – surgical resection and a three-drug regimen of methotrexate, doxorubicin, and cisplatin – and is the same for patients with localized or metastatic disease, despite the vast difference in prognosis between these groups.

Hematopoietic cell transplantation

HCT is not commonly used to treat osteosarcoma, despite the lack of effective therapy for relapsed patients and the poor prognosis of patients who present with metastases. In fact, the EBMT received reports of only seven patients transplanted for osteosarcoma as of 1992. Of the five patients with measurable disease, one died of toxicity, three had no response and one transplanted in refractory relapse achieved a PR that was improved to CR by surgical excision of lung metastases, and remained in second CR 18 months post-HCT. The two patients transplanted in second CR relapsed 8 and 11 months after HCT [74].

The Cooperative German–Austrian–Swiss Osteosarcoma Study Group retrospectively analyzed 15 patients who received HCT for recurrent osteosarcoma. These patients had all achieved a CR when initially treated. Their sites of relapse were lung in nine patients, lung plus local in two, mediastinal in two and local only in two. All underwent resection of their recurrent disease before HCT; only two had macroscopic residual disease, and neither responded to the high-dose preparative regimen. The preparative regimens all incorporated a combination of etoposide with melphalan or carboplatin, or both. Six patients received two courses of HCT, first with thioTEPA and cyclophosphamide and then with melphalan, but two of these patients died of toxicity. The 3-year OS was 29% and DFS was 20%. Both disease-free survivors received melphalan-based preparative regimens [75].

The Italian Sarcoma Group reported the results of a trial of surgery and tandem autologous HCT for patients with relapsed osteosarcoma. Thirty-two patients were treated. PBPCs were mobilized with cyclophosphamide and etoposide. Fourteen patients had surgery before chemotherapy and 11 had surgery at the completion of all therapy. Eleven of 32 patients were in CR before their first course of high-dose therapy, while 21 were treated with gross disease. At the end of treatment, 25 patients (78%) were in CR, six were in PD, and one had died of toxicity. Despite this excellent response rate, 3-year OS was only 20%, and 3-year DFS was only 12% [76].

These few studies suggest that there is little if any benefit to high-dose chemotherapy with HCT for relapsed osteosarcoma. In light of the lack of benefit to treatment intensification for patients with a poor response to neoadjuvant therapy, this suggests that future improvements in the treatment of patients with relapsed or refractory osteosarcoma will not come from treatment intensification, and that new approaches are required.

Retinoblastoma

Epidemiology and etiology

Retinoblastoma affects one child of every 18,000 live births in the United States in the first 5 years of life [77]. Approximately 25–30% of cases are bilateral, and follow an autosomal dominant inheritance pattern; in addition, approximately 10–15% of unilateral cases are hereditary. The observation that hereditary cases occur earlier in life and are bilateral or multifocal was key in the development of Knudson's two-hit model of carcinogenesis [39]. Knudson proposed that patients who inherit one mutation need only a single somatic mutation in a given cell for malignant transformation, while sporadic cases required the accumulation of two independent somatic mutations to transform a single cell.

Molecular and cellular biology

The postulated inactivation of a tumor suppressor gene was confirmed by the demonstration of loss of heterozygosity at 13q14 [78]. The cloning of the *RB1* tumor suppressor gene [79] was a pivotal step in understanding the pathogenesis of retinoblastoma and also a tumor suppressor gene involved in many other malignancies. The RB1 gene product is commonly absent in both sporadic and heritable retinoblastoma, as predicted by the two-hit model. Normally, RB1 mRNA is ubiquitously expressed, and encodes a nuclear protein with DNA binding sequences [80]. The protein is unphosphorylated in quiescent cells, but is phosphorylated in proliferating cells [79] and regulates the cell cycle in its unphosphorylated form by binding the E2F1 transcription factor [81]. In addition to loss of function of both alleles of the *RB1* gene, amplification of *MDMX* (65%) or *MDM2* (10%) occurs in the majority of human retinoblastomas, inactivating p53 and promoting the development of retinoblastoma [82].

Clinical description

Retinoblastoma typically presents as leukocoria when the tumor becomes visible through the pupil or causes retinal detachment or vitreous hemorrhage. Patients may lose central vision, leading to strabismus. Less commonly, heterochromia can result from neovascularization of the iris. In developing countries, the diagnosis may not be made until the eye becomes enlarged or the orbit is invaded, but extensive disease is uncommon in the United States. In patients with germline *RB1* mutations, new primary tumors may appear in the retinas for the first 3–5 years of life. In addition to bilateral retinoblastoma, these patients are at risk for primitive neuroectodermal tumors in the pineal and suprasellar regions, a presentation termed trilateral retinoblastoma.

Non-transplant approaches

Early detection of retinoblastoma is the norm, and the treatment outcome of patients with localized disease is excellent. Enucleation is curative for early solitary unilateral lesions, while adjuvant chemotherapy is indicated for patients with pathologic risk factors such as extension beyond the cribriform plate. Orbital extension is curable in 60–85% of patients with multimodal therapy, including external beam irradiation and systemic chemotherapy. In patients with bilateral disease, additional methods are used in an effort to preserve useful vision, including brachytherapy, cryotherapy, laser photocoagulation, and systemic and also subconjunctival or intra-arterial chemotherapy. In contrast, advanced central nervous system (CNS) involvement and "trilateral retinoblastoma" [83] are incurable: multimodal therapy including systemic and intrathecal chemotherapy and cranial irradiation has produced remissions, which, however, have not been durable [84]. Hematogenous dissemination to bone, marrow, and viscera and involvement of soft tissue and lymph nodes carry an extremely poor prognosis. Only ifosfamide and CY have efficacy as single agents and have produced CRs when used in two- and three-drug combinations [85].

HCT as consolidation for disseminated disease

There are several individual case reports and small case series [86–89] of HCT for patients in second CR after metastatic recurrence in bone or marrow. These reports describe a total of 25 patients, of whom only five experienced further progression of their disease. The remaining patients had no evidence of disease 18–107 months after relapse.

The SFOP formally evaluated HCT for patients with high-risk retinoblastoma, using a single-arm protocol active from 1989 to 1994 [90]. The target population was patients with extraocular disease or histologic evidence of tumor at the cut end of the optic nerve or its subarachnoid space. Measurable extraocular disease had to be chemosensitive in order for patients to be eligible to proceed to HCT. During the study period, 34 high-risk patients were identified: eight with microscopic residual optic nerve involvement, 10 with extraocular disease confined to the orbit, 11 with extraocular involvement including distant bones or marrow, and five with CNS involvement. Nine patients did not proceed to HCT because of CNS progression [6], parental refusal [2], or toxicity [1]. Therefore, 25 patients (six with optic nerve, seven with orbital disease, eight with distant bone or marrow disease, and four with CNS involvement) proceeded to HCT with a preparatory regimen of carboplatin 1250–1750 mg/m^2, etoposide 1750 mg/m^2, and cyclophosphamide 3200 mg/m^2. Five of six patients who had measurable disease at the time of HCT achieved CR. On an intention-to-treat basis, five of eight patients with optic nerve involvement, six of 10 patients with orbital involvement, five of 11 patients with bone or marrow involvement, and one of five patients with CNS involvement survived with no evidence of disease. Compared with historical results using much longer courses of conventional chemotherapy, this approach produced comparable survival for patients with optic nerve or orbital involvement, and was superior for patients with distant bone or marrow involvement [90]. More recently, the group from the Memorial Sloan Kettering Cancer Center reported their results intensifying conventional therapy with high-dose chemotherapy and stem-cell support for patients with stage 4a and 4b metastatic retinoblastoma [91,92]. Fifteen consecutive patients who presented with stage 4a retinoblastoma were treated on a protocol that included an alkylator-based induction chemotherapy regimen followed by high-dose chemotherapy with autologous stem-cell support. Of the 13 patients who completed this therapy, 10 remained disease free with a median follow-up of 103 months. For stage 4b retinoblastoma patients, a retrospective review identified eight patients from six centers presenting between October 2000 and January 2006. Of the five patients who were able to receive autologous HCT, two were long-term survivors at 40 and 101 months.

One potential benefit to this approach for advanced-stage disease is the possibility of avoiding bilateral enucleation and external beam radiation therapy, which carry a significant risk for secondary malignancies and also facial deformities. Lee et al. reported a regimen utilizing tandem autologous HCT for bilateral retinoblastoma without external beam radiation therapy. Of 14 patients who presented with a bilateral retinoblastoma, nine underwent tandem autologous HCT. The regimen was well tolerated and all nine patients survived with at least one eye after treatment [93].

Based on these promising data in a condition with otherwise dismal prognosis, the current COG study, ARET0321, aims to determine the efficacy of autologous HCT in a multicenter collaborative study. Patients with metastatic disease without CNS involvement (stage 4a) and metastatic disease with CNS involvement (trilateral or stage 4b) will receive high-dose chemotherapy consolidation with carboplatin, thioTEPA, and etoposide if there is more than partial response after an induction regimen including cisplatin, vincristine, etoposide and cyclophosphamide. This will be followed by an autologous stem-cell infusion, then response-adapted radiation therapy.

Desmoplastic small round cell tumor

Epidemiology and etiology

Desmoplastic small round cell tumor (DSRCT) is a highly malignant abdominal small round blue cell tumor with epithelial, mesenchymal, and neural characteristics, initially described in 1991 [94]. It occurs in children and young adults and only 101 cases were reported between 1989 and 1996. There is a strong male predominance and a median age at diagnosis of 25 years. There are no known associations with exposure to carcinogens [95].

Molecular and cellular biology

A balanced translocation, t(11;22)(p13;q12), results in *EWS–WT1* fusion transcripts considered diagnostic of DSRCT. As with the *EWS–FLI-1* fusion transcripts of Ewing sarcoma, these fusion transcripts retain the amino-terminal effector domain of EWS and replace its DNA binding domain with that of its fusion partner. The fusion transcripts are heterogeneous both within and between tumors with respect to the use of specific EWS and WT1 exons, the presence of internal deletions, and insertion of heterologous DNA. However, the splice variants are in-frame and the chimeric proteins bind *WT1* response elements [96].

The transcriptional regulatory activity of EWS–WT1 differs from that of WT1. The platelet-derived growth factor A chain (PDGFA) is directly induced by EWS–WT1, and may contribute the stromal content of DSRCT [97]. In addition, expression of insulin-like growth factor-1 receptor (IGF-1-R), which has mitotic and antiapoptotic functions, is normally repressed by WT1, but is activated by EWS–WT1 chimeras [98]. The interleukin-2/15 receptor beta chain promotes cell growth by downstream activation of STAT3 and STAT5 [99]. The brain-specific angiogenesis inhibitor 1-associated protein 3 (BAIAP3) when expressed ectopically in tumor cells enhances anchorage-independent and low serum growth and may assist the secretion of FGF-1 and -2 to produce the desmoplastic reaction characteristic of the tumor [100]. The leucine-rich repeat containing 15 (*LRRC15*) gene normally expressed only in placenta in the trophoblast cell layer responsible for implantation of the embryo, is hypothesized to contribute to the invasiveness of DSRCT [101].

Clinical description

Patients typically present with abdominal distension and pain, with constipation a common associated finding [102]. DSRCTs most commonly grow in the peritoneal cavity, with large masses and multiple implants along serosal surfaces, and may metastasize to lymph nodes, liver, lung, bone, spleen, kidney, and pleura. Characteristic computed tomography (CT) findings are of bulky intra-abdominal soft tissue masses without a distinct organ of origin [103]. Unusual sites of primary involvement include kidney, lung, bone, and pancreas. Exploratory laparotomy reveals large, firm, multinodular tumors with smooth surfaces. Conventional microscopy reveals sharply demarcated clusters of small round tumor cells embedded in a dense desmoplastic stroma. Immunohistochemical staining reveals expression of epithelial (cytokeratin, epithelial membrane antigen), mesenchymal (vimentin), myogenic (desmin), and neural (neuron-specific enolase, CD56) markers [104,105]. WT1 immunoreactivity results from expression of the EWS–WT1 fusion transcript. CD99 (MIC2), commonly used to identify Ewing family tumors, is also commonly positive [106].

Non-transplant approaches

This tumor is often initially responsive to chemotherapy such as combinations of doxorubicin, cisplatin, CY, etoposide, and fluorouracil. However, the outcome has been dismal, with median survival of only 17 months (range 3–72 months); as of 1996, only 7/101 reported patients were alive a median of 24 months (range 4–48 months) from diagnosis [107]. Several more extensive series have been reported from single institutions [95,102,108,109]. Cumulatively, these series suggest that complete resection of desmoplastic small cell tumors contributes to long-term survival, but these tumors are generally not resectable at initial presentation; they are usually initially chemosensitive, but the short duration of responses warrants attempts at consolidation with intensified therapy.

Hematopoietic cell transplantation

There are a few reported cases of HCT as salvage therapy for recurrent or refractory desmoplastic small cell tumor, but none resulted in long-term survival [107,110,111]. In the Memorial Sloan Kettering Cancer Center series, the intention was to consolidate first responses of patients with initially unresectable disease with HCT, but two of five patients did not proceed to HCT because of the toxicity of the initial chemotherapy. Three patients with initially unresectable disease received HCT with thioTEPA and carboplatin in first response, two in CR, and one in PR. The patient transplanted in PR progressed at 15 months. The patients transplanted in CR were alive without evidence of disease 13 and 34 months from initiation of therapy [108]. The St. Jude DSRCT series included four patients who underwent autologous HCT. Two patients who received HCT after radiation therapy died of toxicity. Of the two other patients, the one transplanted in CR and treated with radiation after HCT remained alive without disease 16 months after completion of therapy. In an adult population, entered on a protocol with intent to transplant in Milan, of 10 patients with DSRCT, only five achieved a PR to induction therapy with ifosfamide, vincristine, and etoposide and proceeded to HCT with a melphalan-based preparative regimen. None of the patients were converted to CR or cleared their EWS–WT1 fusion transcripts after high-dose melphalan, and all progressed within 12 months [112]. One of these patients subsequently received an allogeneic HCT after reduced-intensity conditioning, and cleared his fusion transcript after developing grade III acute graft-versus-host disease (GVHD) [112], suggesting the presence of a graft-versus-DSRCT effect. Success has been achieved in small series exploring more intensive alkylator-based approaches. All four patients with DSRCT treated in first partial ($n = 2$) or complete ($n = 2$) response with busulfan, melphalan, and thioTEPA, with or without amifostine remained alive after 1.1–6.4 years (median 3.2 years) of follow-up, of whom only one had progressive disease [113]. Three patients with DSRCT treated with VACIME with repeated PBPC support became long-term survivors with no evidence of disease 25–66 months from diagnosis [114]. In the European RMS4.99 protocol, patients were treated with autologous HCT after initial surgical staging and induction chemotherapy. Seven out of 10 patients showed a partial response to HCT and three achieved a CR. Only three of these 10 were reported as alive, including one patient who was only 7 months since discharge [115]. More recently, the Center for International Blood and Marrow Transplant Research (CIBMTR) reported their experience with high-dose chemotherapy with autologous stem-cell support for DSRCT. A total of 36 patients underwent high-dose chemotherapy with autologous stem-cell support between 1999 and 2007. Treatment-related mortality (TRM) was low with one death in the first 100 days, while the DFS for patients who were in CR pre-transplant was 92% at 1 year and 75% at 3 years, compared with 35% at 1 year and 9% at 3 years for patients who were not in CR. The median OS for patients who were not in CR was 21 months, which is slightly longer then historic controls, suggesting some benefit to autologous HCT [116]. In summary, the role of HCT remains to be defined for patients with DSRCT, but the few long-term survivors have been patients who have obtained complete surgical resections and autologous HCT may contribute to survival in both patients who have achieved CR and those who did not achieve CR after conventional chemotherapy.

HCT for other rare pediatric solid tumors

Pleuropulmonary blastoma is a rare tumor, approximately 100 cases of which have been reported. The primary therapy is surgical excision, without adjuvant therapy. Because of the histologic resemblance to soft tissue sarcoma and Wilms tumor, chemotherapy regimens designed for these entities have been used. Such combination chemotherapy has produced 30–40% DFS [117]. There are very few reports of the use of HCT in patients with pleuropulmonary blastoma. Melphalan-based HCT was used for progressive disease [118], one for chemotherapy-sensitive microscopic residual disease [117] for consolidation after complete surgical resection in first relapse [119], and one for refractory metastatic disease [120]. The patients with bulky refractory disease progressed soon after HCT, but the patients with microscopic residual disease and complete surgical resection were alive in continuous CR at 12 and 31 months respectively after HCT.

Esthesioneuroblastoma is a rare tumor, arising from olfactory epithelium; of over 240 cases in the literature, only 21% are pediatric. The behavior of this tumor may be more aggressive in childhood. It has been suggested that esthesioneuroblastoma may be a member of the Ewing sarcoma family on the basis of a t(11;22) in 2/3 cell lines derived from metastatic esthesioneuroblastoma cases. However, unlike Ewing tumors, esthesioneuroblastomas do not express MIC-2, and primary esthesioneuroblastomas are characterized by trisomy 8, not t(11;22) [121]. In a single-institution series, long-term survival was achieved in 3/5 adult patients salvaged with CY-containing HCT preparatory regimens versus 4/17 salvaged with conventional chemotherapy [122]. One adolescent was treated for a cervical nodal recurrence with modified radical neck dissection, and consolidation with high-dose carboplatin, etoposide, melphalan, and HCT, and had no evidence of disease 1 year later [123]. In a case series from Japan, 12 patients with esthesioneuroblastoma were diagnosed between 2000 and 2003, including four who received HCT following induction chemotherapy, who were long-term survivors [124]. Although this was an uncontrolled study that also included patients who were transplanted after surgery, it is a promising lead for patients with relapsed and recurrent esthesioneuroblastoma.

Future directions

Patterns of failure

After HCT for Ewing tumors, the majority of relapses are metastatic, most commonly in lung and secondly in bone [21,125]. A more recent analysis indicated that bony failures often occur in involved bones outside the local radiation field, and in lesions detected by magnetic resonance imaging (MRI) or positron emission tomography (PET) scan, but not bone scan [126]. Possible solutions to this problem include irradiating the lungs and the entire involved bone system prophylactically and incorporating the use of MRI and/or PET scans in staging before HCT.

In contrast, failures after HCT for rhabdomyosarcoma tend to occur early, at a median of 4 months after HCT, almost always (23/26 cases) in previously known sites [33]. This observation argues for the use of local radiation to all previously known sites of disease.

Regimens

Role of total body irradiation

For all but the most radiosensitive tumors, the dose of radiation therapy that can be delivered as TBI is inadequate for the control of bulky tumors. Doses of adjuvant radiation demonstrated to control the majority of microscopic residual disease (typically 10^6–10^8 cells) exceed the maximum tolerable doses of TBI [127]. However, the relationship between the dose of radiation and the percentage reduction in risk of recurrence appears to be linear. Extrapolating from these dose–risk data, zero reduction in risk occurs at a dose between 0 and 5 Gy, indicating that there is a low threshold, if any, for tumor cell killing by radiation [128]. Therefore, the modest doses of radiation feasible as TBI may be expected to control very small micrometastases (perhaps 10^2–10^4 cells).

The question of whether TBI is a necessary or desirable component of the high-dose cytoreductive regimen has been addressed retrospectively by the EBMT. For rhabdomyosarcoma patients, addition of TBI to melphalan appears only to increase toxicity [32]. A retrospective analysis of the German–Austrian Pediatric BMT Group also found no benefit of 12 Gy hyperfractionated TBI added to melphalan, etoposide, and carboplatin [33]. For Ewing sarcomas, the EBMTR observed that patients receiving TBI fared worse ($n = 30$, 19% EFS) than those receiving high-dose chemotherapy alone ($n = 33$, 34% EFS); the best results were obtained with chemotherapy combinations that included busulfan (51% EFS) [129].

Tandem transplants

A substantial number of tandem transplants, in which two or more HCTs are performed with minimal recovery time between transplants, have already been performed in an attempt to improve tumor control. This approach is most likely to be effective if there is more than one active and non-cross-resistant cytoreductive regimen, without cumulative toxicity. Even if a single regimen must be used twice, if a similar log cell kill may be obtained in a second course, repeated application may overcome problems of delivery of drug to the core of a bulky tumor. Whether tandem HCTs as delivered so far have been beneficial is controversial. The results of several institutional series indicate longer responses in patients receiving multiple courses of high-dose therapy [130,131]. However, the cumulative experience of the EBMT provides no convincing evidence in favor of double transplants in Ewing sarcoma [129]. In addition, at least with carboplatin and etoposide, no patient improved their response with a second course [132].

The use of PBPCs instead of bone marrow may improve the efficacy of tandem transplants because faster hematopoietic recovery may allow greater treatment intensity. Two courses of melphalan 100 mg/m^2 could consistently be administered with PBPC rescue within 21–34 days (median 24 days) with no change in pharmacokinetics or pharmacodynamics [133]. A limited-institution pilot study demonstrated the feasibility of tandem PBPC transplant for metastatic neuroblastoma or sarcoma, delivering CY 3600 mg/m^2, etoposide 2400 mg/m^2, and carboplatin 2000 mg/m^2, followed within 28–42 days by melphalan 180 mg/m^2 and TBI 12 Gy in 46 of 51 eligible patients [134,135]. Of the five patients who received only one HCT, three were by patient request and two were ineligible to proceed because of liver toxicity. There were four toxic deaths (9%). Three courses of HCT have been administered to 17 of 22 patients, with one toxic death in the acute transplant period [136]. Although short-term toxicity may be acceptable, this pilot trial shows the importance of long-term follow-up, because three patients developed pancytopenia as a late complication, two with graft failure and one with monosomy 7-associated myelodysplastic syndrome.

A novel variation is the use of double high-dose therapy with only one HCT procedure [137]. Because the dose-limiting toxicity of melphalan and thioTEPA in the setting of HCT is mucosal, and the affected tissues recover relatively quickly, two cycles can be given 1 week apart, and patients rescued with a single PBPC product after the second cycle. This strategy allows the safe delivery of thioTEPA 1000 mg/m^2 and melphalan 280 mg/m^2 over 9 days. The indications for HCT were heterogeneous in this phase I/II trial, but

10/13 patients entering HCT in CR and 6/13 patients entering HCT with residual disease were alive with no evidence of disease 15–59 months (median 35 months(after transplantation. Of particular interest is that all three patients with hepatoblastoma who entered HCT with persistent α-fetoprotein elevation achieved long-term CR [137].

Targeted therapy

Targeted therapeutics refers to treatments designed to exploit a biologic feature of the tumor to eradicate it. Examples of targeted therapies include tyrosine kinase inhibitors such as imatinib mesylate and ligand-targeted monoclonal antibodies such as rituximab. There are two significant ongoing applications of targeted therapy for pediatric solid tumors that involve HCT: [^{131}I]-*m*-iodobenzylguanidine (MIBG) for the treatment of neuroblastoma (see Chapter 63) and [^{153}Sm]ethylenediaminetetramethylenephosphonic acid (EDTMP) for the treatment of osteosarcoma. Each of these treatments utilizes a fundamental characteristic of the tumor to direct a radiopharmaceutical agent specifically to the tumor, and ameliorates the myelosuppression with autologous hematopoietic cell support.

[^{153}Sm]EDTMP consists of a radioisotope (^{153}Sm) conjugated to a tetraphosphonate compound that localizes to sites of bone turnover, such as a metastatic bone lesion. Because [^{153}Sm]EDTMP targets bone lesions by a mechanism similar to that of the radiotracer used in a bone scan, lesions that are visible on bone scan, including both primary osteosarcoma and metastatic deposits, are targeted by this agent. Radioactive decay of the ^{153}Sm yields a medium=-energy electron (β particle) and a low-energy photon. The electron has a very short pathlength (1–2 mm), thus providing exquisitely precise targeting of the cytotoxic energy. The photon can be detected using the same instrument as used for a diagnostic bone scan, allowing uptake at a target tumor to be confirmed and the amount of radiation delivered to the tumor to be measured. The half-life of ^{153}Sm is very short (46 hours), facilitating handling. The compound was originally tested in adult patients with bone metastases from carcinomas, such as breast and prostate cancer, and is approved by the US Food and Drug Administration (FDA) for palliation of painful metastases. In 2002, Anderson et al. published the results of a phase I study of [^{153}Sm]EDTMP for the treatment of high-risk osteosarcoma patients [138]. Thirty patients were treated with 1–30 mCi/kg of [^{153}Sm]EDTMP. Because this compound significantly depresses bone marrow function, patients were rescued with an infusion of autologous PBPCs 14 days after treatment. Other than low blood counts, the only side effect was transient hypocalcemia in patients treated with the highest dose. All of the patients began the trial requiring narcotics for pain relief, and every patient experienced a decrease or elimination of their narcotic requirement. In an attempt to improve efficacy, this group subsequently treated patients with gemcitabine, a chemotherapeutic agent that is thought also to act as a radiation sensitizer [139]. Fourteen patients were treated with high-dose [^{153}Sm]EDTMP followed 1 day later by gemcitabine. After 2 weeks, autologous PBPCs were reinfused. At 6–8 weeks of follow-up, there were six partial remissions and two mixed responses, but none of these responses were durable. In another study, patients with recurrent or refractory osteosarcoma were treated with tandem doses of [^{153}Sm]EDTMP. The first dose was low, allowing count recovery within 6 weeks, and the second was higher and required peripheral blood stem-cell support. Although none of the patients had better than disease stabilization by RECIST 1.1 criteria, there was a dose–response relationship between tumor-absorbed radiation dose and change in tumor volume, suggesting that this approach can deliver cytotoxic, targeted radiation safely, and that finding a way to increase dose might improve treatment response [140]. Hence [^{153}Sm]EDTMP shows promise for treating osteosarcoma, but further work is required to determine its optimal use.

Hematopoietic cell grafts

The source of the graft: peripheral blood hematopoietic cells versus bone marrow

It is now recognized that mobilizing and collecting PBPCs is feasible in children despite their small size and the intensity of the pediatric chemotherapy regimens, and PBPCs produce faster engraftment [141] and immune reconstitution [142] than bone marrow. Although tumor cells can frequently be detected in mobilized PBPC grafts [143,144], the question of whether the purging of autologous hematopoietic cells can improve outcome remains to be answered. Few data are available regarding the relationship between tumor contamination of the graft and survival outcomes, but long-term DFS can occur in patients with Ewing sarcoma who receive PBPC grafts containing detectable fusion transcript [145]. In rhabdomyosarcoma, the major determinant of long-term survival after HCT was whether CR was achieved prior to HCT [32], and 23 relapses occurred in previously known sites, compared with only three in new metastatic sites [33], suggesting that tumor control in the body, not reinfusion of tumor cells in the graft, is the major problem.

Allogeneic HCT

The role of allogeneic HCT in pediatric solid tumors is being explored. Allogeneic transplantation carries the risk of GVHD, but its potential benefits include the absence of tumor cells in the graft and perhaps an immunologic antitumor effect. For rhabdomyosarcoma, the German–Austrian Pediatric BMT Group found no evidence of benefit from allogeneic HCT, as none of five allogeneic HCT recipients survived [33]. In addition, donor lymphocyte infusion was reported to be ineffective in a case of relapsed rhabdomyosarcoma [146], but since the patient did not have measurable disease at the time of donor lymphocyte infusion and did not develop GVHD, this case did not address the activity of an effective immune response. A CR after reduced-intensity matched-sibling peripheral blood HCT for a patient who had failed two prior lines of therapy including autologous HCT suggests benefit from an allogeneic effect [147]. For Ewing tumors, there was a trend towards better outcome with allogeneic HCT (50% survival versus 23% survival of the entire group of 27 allografted patients at a median of 56 months) in the single-institution experience with (TB)I/ME(C) of Vienna, from 1984 to 1996 [148]. With longer follow-up, incorporating the experience from Düsseldorf, DFS after allogeneic HCT was not better than after autologous HCT for Ewing tumors because of higher rates of non-relapse mortality [149]. In the multicenter study published in 2011 from the EBMT, APBMT, PRST, and MetaEICESS, outcomes of 87 patients who received an allogeneic HCT for Ewing sarcoma were reported. Interestingly, there was no difference in OS between reduced-intensity ($n = 50$) and high-intensity ($n = 37$) conditioning. Although the reduced-intensity group had a higher risk of relapse, the high-intensity group had a higher risk of fatal complications, leading to comparable OS. Although this result suggests that there is no clinically relevant graft-versus-tumor effect in Ewing sarcoma, there are informative case reports of patients with recurrent, metastatic Ewing sarcoma who underwent allogeneic HCT and whose disease responded to withdrawal of immune suppression [147] or institution of interleukin-2 (IL-2) therapy [150] with subsequent development of acute GVHD.

Because sarcoma patients coming to transplant are always heavily pretreated, TRM is a substantial concern. This prompted the investigation of reduced-intensity conditioning regimens for these patients. The Pediatric Oncology Branch at NIH recently reported results of 23 patients with ultra-high-risk sarcomas who underwent reduced-intensity allogeneic HCT. All patients engrafted promptly with no peri-transplantation mortality. Three of the seven patients transplanted without overt disease (42%) remained alive, with a median survival of 29.0 months, compared with a median survival of 14.5 months for those transplanted with radiographically evident disease [151]. This approach was feasible in this very high-risk patient population, and may provide a survival benefit for those who go to transplant in remission.

Overall, few data are available regarding allogeneic HCT for pediatric solid tumors. This probably results largely from the role of neuroblastoma as the prototypical poor prognosis pediatric solid tumor and the clear consensus that there is no role for allogeneic transplantation in neuroblastoma [152,153]. The lack of benefit from allogeneic HCT indicates that tumor contamination of autologous grafts is not a major source of relapse, and that alloreactive cytotoxic T-lymphocytes (CTLs) are not substantially effective against high-risk pediatric solid tumors. However, a potentially important biologic difference between neuroblastoma and sarcomas is that in vitro, neuroblastoma cells are poor targets for CTLs, whereas sarcoma cells are excellent CTL targets [154]. Hence the role of HCT for ESFT and other sarcomas remains an unanswered question worthy of further study.

Immunotherapy

Rhabdomyosarcomas and Ewing tumors are targets both for natural killer (NK) cells and for CTLs [155], and tumor-infiltrating lymphocytes isolated from osteosarcomas can lyse allogeneic osteosarcoma cell lines [156]. The possibility that these immunologic effector mechanisms may be clinically important in high-risk Ewing tumors was suggested in the pilot trial of hyperfractionated TBI with melphalan and etoposide conducted in Vienna and Düsseldorf. In their initial cohort of 17 patients with very high-risk Ewing tumors, 3/4 allograft recipients were disease-free survivors, along with 3/5 autograft recipients treated with IL-2 versus 2/8 autograft patients without IL-2 [157]. The advantage of IL-2 after autografting persisted in a larger EICESS cohort treated using the same approach: DFS was 52% for patients receiving IL-2 after HCT versus 22% without IL-2 ($p < 0.05$) [126]. The possible effector mechanisms involved in patients receiving IL-2 after HCT have been explored, and expansion of T and NK cell numbers, but not NK/T cells, was demonstrated. NK activity was enhanced, in spite of increased activation of the CD94 inhibitor receptor [158].

The National Cancer Institute has conducted a pilot trial of tumor-specific vaccination for Ewing sarcoma and alveolar rhabdomyosarcoma, based on pulsing dendritic cells with the unique EWS/Fli-1 and PAX3/FKHR fusion peptides associated with the t(11;22) and t(2;13) translocations characteristic of these tumors [159]. Sixteen patients were enrolled, and 15 received at least one vaccination. Unfortunately, most patients experienced tumor progression during the first 6-week vaccination cycle, so only four patients received two or more cycles of vaccination. One of these four patients had a mixed response, and another had a fusion peptide-specific lymphocyte proliferative response. This study is important not only because of the encouraging suggestion of some immunologic activity against tumor, but also because it identified several pitfalls of immunotherapy. These patients had severely impaired immunity and large tumor burdens, and the immature circulating dendritic cells used may actually suppress immune responses [159]. Moreover, a single peptide antigen was used, with uncertain human leukocyte antigen (HLA) restriction and cell-surface expression, and the tumor itself may have induced tolerance or anergy in autologous lymphocytes.

An alternative strategy of generating antitumor CTL cell lines ex vivo has been explored in Ewing sarcoma patients. Specific antitumor CTLs were generated from three patients, all of whom had undergone prior autologous HCT, after two or more cycles of stimulation of autologous PBMCs with autologous peripheral blood-derived dendritic cells, $CD4^+$ lymphocytes, and irradiated early passage autologous tumor cells [160]. Although the approach is labor intensive, potential advantages include the response to both unknown and previously identified tumor antigens and the reduced potential for escape by loss of antigen expression. The clinical utility of such cell lines has yet to be demonstrated.

Another strategy in maximizing the antitumor effect after allogeneic transplant has been to manipulate NK cells. NK cell alloreactivity depends on inhibitory killer immunoglobulin-like receptor (KIR) mismatch [161]. In a pilot study, three patients with refractory solid tumors received a haploidentical HCT, and two patients who were known to have a KIR mismatch with the donor demonstrated tumor response (although one eventually progressed and died of disease) [162]. Multiple trials are currently being conducted with various methods to maximize this antitumor effect of NK cells, such as IL-15 activation and KIR mismatch. The development of reduced-intensity allogeneic HCT offers an alternative avenue to immunotherapy for pediatric solid tumors, but novel approaches will be required to demonstrate activity if this approach is beneficial only in minimal residual disease.

Conclusion

The prognosis of patients with metastatic, recurrent, or refractory pediatric solid tumors is dismal. High-dose preparatory regimens with HCT have demonstrated activity against a broad spectrum of the pediatric solid tumors. HCT has produced promising results in the treatment of Ewing tumors. Prospective randomized trials of HCT versus conventional chemotherapy are in progress for patients with poor-prognosis Ewing tumors and are being considered for high-risk recurrent Wilms tumor. For less common indications, phase I and II trials are appropriate. Approaches now being investigated to improve the efficacy of HCT for pediatric solid tumors include tandem HCT, targeted therapy, chemoprotection, and targeted immunotherapy, possibly via allogeneic HCT.

CHAPTER 65

Hematopoietic Cell Therapy for Human Immunodeficiency Virus Infection

Amrita Krishnan, Joseph Alvarnas, John J. Rossi and John A. Zaia
City of Hope Medical Center, Duarte, CA, USA

Introduction

In the two decades since Holland and Saral first suggested a potential role for HCT in eliminating the HIV reservoir, [1], the field has evolved to a point at which hematopoietic stem/progenitor cell (HSPC) transplantation (HSCT) has a credible potential in treating patients with human immunodeficiency virus type 1 (HIV-1) infection. The predominant place for the use of HSCT in the setting of HIV-1 infection is, of course, in the treatment of patients with acquired immune deficiency syndrome (AIDS) who have hematologic malignancies. In this regard, the standard of care now provides autologous HSCT as successful salvage treatment in AIDS patients with high-risk or refractory lymphoma. More importantly, however, allogeneic HSCT for leukemia has established this approach as a potentially curative treatment of AIDS [2]. The future may show a role for HSCT even in the management of the HIV-1-infected patient without malignancy.

The single case report of allogeneic transplantation of HSPCs, using a matched unrelated donor with genetic resistance to HIV-1, resurrected the question of whether there is a curative role of allogeneic HSCT for HIV/AIDS [2]. Even without intrinsic cellular resistance of donor cells, it has recently been suggested that the allogeneic effect following HSCT could alter the HIV-1 reservoir in ways that allow combination antiretroviral therapy (cART) to control infection effectively [3]. There will undoubtedly be more interest in the use of HSCT in HIV/AIDS, hence it is increasingly important to understand how to manage the HIV-1-infected patient during this procedure. At the same time, the potential for genetic modification of autologous HSPCs to reproduce HIV-1 resistance of the immune system continues to develop as another stem-cell-based strategy [4]. This chapter highlights the current understanding of the pathogenesis of AIDS and the rationale for gene therapy of HIV/AIDS, and presents a review of recent studies of both autologous and allogeneic stem-cell transplantation in HIV/AIDS patients. Guidelines for the management of the HIV-1-infected patient during HSCT are presented, recognizing that these stem-cell-based therapies for AIDS patients provide new information leading to better control of HIV-1 infection.

The pathogenesis of HIV-1 infection and AIDS

HIV-1 infection

HIV-1 infection is associated with three phases: primary infection, a chronic phase, and a terminal phase of AIDS [5]. Following primary infection, which lasts 3–6 weeks, there is an immune response to the virus and establishment of a relatively stable level of HIV-1 RNA in plasma and in fixed tissue-based reservoir. The chronic phase of infection can last 10 years or more, but eventually the immune system fails, the virus develops a tropism for T cells, and a terminal phase in which there is more rapid loss of CD4$^+$ lymphocytes, more profound immunodeficiency, and the development of infections or malignancies that define AIDS.

The initial HIV-1 infection follows contact with infectious body fluids and gains entry into susceptible cells following interaction of the viral envelope proteins and a primary cellular receptor, CD4 (reviewed by Shaw and Hunter [6]). Of hematopoietic interest, chemokine receptors, primarily CXCR4 and CCR5, are coreceptors required for viral entry [7,8]. These chemokines are from a diverse family of peptides that bind to receptors and activate immune and/or inflammatory responses [9]. The C–C chemokine receptor, CCR5, is the major coreceptor for macrophage-tropic (R5) HIV-1, and a C–X–C chemokine receptor, CXCR4, is used for entry of T-tropic (X4) strains of HIV-1 [6]. Other chemokine coreceptors can fulfill this coreceptor function in vitro, but CCR5 and CXCR4 are most critically important in vivo.

The actual entry of virus into a cell follows the formation of a heterotrimer complex, consisting of the HIV-1 envelope, the CD4 receptor, and the chemokine coreceptor, that forces an alteration of the membrane that exposes a peptide domain contained within the HIV-1 fusion protein (gp41) [10]. The engagement of the gp41 fusion peptide with the target cell membrane culminates in penetration of HIV-1 into the cell with subsequent movement into the nucleus. Infection can then be influenced by natural cell factors, many of which are only beginning to be understood [11]. For example, the native ligands for CCR5, such as RANTES and MIP-1α, and stromal-derived factor 1 for CXCR4, can compete with HIV-1 for binding to these virus coreceptors and inhibit HIV infection [12,13]. A meta-analysis of patient cohorts has shown that only the CCR5-Δ32 and the CCR2-64I mutations are associated with strong protective effects from progression of HIV-1 infection [14]. In addition, there are cellular proteins that act as restriction factors to inhibit HIV-1 replication and alter pathogenesis, such as APOBEC3G, TRIM5α, tetherin, SAMHD1, and others [15]. Undoubtedly, additional targets for future

treatment of HIV-1 will derive from the genome-wide analyses that uncover new cellular inhibitors of HIV-1 [11].

HIV-1-infected mucosal tissues are areas rich in CCR5$^+$ dendritic cells (DCs) and T lymphocytes (T cells). HIV-1 can cross the mucosal barrier by various mechanisms, including epithelial barrier breach, transcytosis, and transport in infected DCs [5], and, once across the mucosa, the virus infects CCR5$^+$ DCs, which propagate the infection locally to T cells and to draining lymph nodes [16]. DCs of the myeloid lineage are infected predominantly with R5 strains of HIV-1, although infection with dual-tropic isolates of HIV-1, exhibiting the capacity to use CCR-5 and/or CXCR-4 for entry, can infect DCs. Expression of the coreceptors is regulated by a complex cytokine network that influences HIV-1 replication in these cells [17]. Therefore, factors that stimulate cytokine release, such as co-infection with other microbes and microbial antigen translocation from the gut [18], can influence the homeostatic activation or inhibition of DCs and serve as important factors that will affect HIV-1 pathogenesis to AIDS.

As shown in primate models and later confirmed in humans [5,19], the primary infection with HIV-1 results in a massive reduction in CD4 cells in the gut-associated lymphoid tissue (GALT). When subsets of CD4$^+$ and CD8$^+$ T cells are studied after primary HIV-1 infection, the major loss of lymphoid elements is in the CCR5$^+$CD4$^+$ T cells [19]. Moreover, this depletion is specific to CD4$^+$ T cells having activated CD69$^+$CD38$^+$HLA-DR$^+$ memory phenotype, and a likely explanation for selective memory T-cell loss with functional disturbance observed in HIV-1-infected humans [5,20].

This preferential depletion of mucosal CD4$^+$ lymphocytes in the GALT, relative to the loss of peripheral blood CD4 cells, remains even after cART treatment brings the HIV-1 viremia under control with near-complete immune recovery of the peripheral blood CD4$^+$ cell population [5]. During the chronic phase of HIV-1 infection, continuing immune activation induces apoptotic processes that lead to the bystander effect producing continued loss of uninfected CD4$^+$ T cells [21]. This further supports a process that maintains the infected cell reservoir [18]. Hence the continued activation of the immune system is thought to drive the persistent loss of CD4$^+$ lymphocytes and is a critical component of disease pathogenesis [22].

The HIV-1 reservoir

The observation that HIV-1 can be isolated from the blood of patients during cART therapy when the HIV-1 RNA levels are below the level of clinical detection suggested a site from which infection could always be recovered [23,24]. The tissue repository of HIV-1-infected cells from which this active replicating HIV-1 is derived is considered the HIV-1 reservoir [25,26]. These cells form a pool from which HIV-1 replication can be rekindled following drug withdrawal or HIV-1 activation. In cases where anti-HIV-1 chemotherapy has been suspended during analytical treatment interruption, a rebound of replicating virus occurs within a few weeks in most patients studied [27]. This rapid reappearance of virus indicates that HIV-1 eradication has not occurred and implies that continuous combination therapy must be maintained at all times, possibly for the life of the patient, in order to maintain control of HIV-1.

The latently infected, resting CD4$^+$ memory lymphocyte, carrying integrated HIV-1 DNA is the primary component of this reservoir [28]. In patients with undetectable infection [<50 genome copies (gc)/mL] on cART, a fraction of the CD4$^+$ cells, usually 0.1–10 infectious units per million (IUPM) cells, contain integrated HIV-1 DNA from which virus can be isolated upon cell activation using a virus outgrowth assay that is the gold standard for measuring the HIV-1 reservoir [25]. Assays for HIV-1 proviral DNA from these cells, including integrated and unintegrated HIV-1 DNA, serve as surrogate measures of the reservoir [29]. Strategies for curing HIV/AIDS target this reservoir and approaches consisting of cytoreductive chemotherapy, immunotherapy, and cell-based treatments are being considered [4,30].

Allogeneic transplantation in HIV/AIDS patients

Chief concerns regarding allogeneic HSCT in the HIV-1-infected patient derive from the need for chronic immunosuppression for graft-versus-host disease (GVHD) prophylaxis in an already immunodeficient patient and the use of cART in a patient receiving such prophylactic therapy. Solid organ transplantation (SOT) laid to rest some of the concerns about graft rejection and demonstrated the feasibility of maintaining HIV-1 infected patients on chronic immunosuppression [31]. The underlying HIV-1 infection is usually not worsened during SOT if patients remain on cART. Recently, with the observations of apparent modification of the HIV-1 reservoir after matched unrelated HSCT, the question has been raised as to whether GVHD might even have a therapeutic affect on the HIV-1 reservoir, and this question is currently under intensive investigation [3].

In the pre-cART era, allogeneic HSCT was resoundingly unsuccessful in an HIV-1-infected recipient, in large part due to procedure-related mortality from infection. Yet a review of multiple case reports reported in the past 25 years indicates that at least 56 patients with HIV-1 infection had undergone allogeneic HSCT by 2010 [32]. Hassett et al. are credited with the first reported use of allogeneic HSCT in AIDS with the unsuccessful treatment of two AIDS patients using matched unrelated donors [33]. A retrospective study by the European Group for Blood and Marrow Transplantation (EBMT) included 30 patients transplanted between 1987 and 2003 and confirmed the negative outcome pre-cART [34]. However, with the introduction of cART, survival post-HSCT appears to have improved [32].

Among these early experiences was a series of HIV-1-infected patients transplanted at Johns Hopkins University [1]. In one patient with relapsed lymphoma, following a fully ablative total body irradiation (TBI)-based conditioning regimen, HSCT was performed using intravenous antiretroviral therapy with the best available agent at the time, zidovudine. The patient engrafted by day +17 but died of lymphoma-related complications by day +47. Of note, the peripheral blood polymerase chain reaction (PCR) was negative for detectable virus post-transplant and analysis of multiple tissues at autopsy did not demonstrate detectable virus [35]. This was the basis for the suggestion by Saral and Holland [1] that combined HSPC therapy and effective antiretroviral therapy might be effective in controlling HIV-1 infection.

With the availability of cART, more successful outcomes were then reported. The first of these was in a 2002 case report of a 33-year-old female with acute myelogenous leukemia, hepatitis C virus infection, and HIV-1 infection who underwent a fully ablative CD34$^+$-selected allogeneic transplant from a human leukocyte antigen (HLA)-matched sibling [36]. The patient was on cART prior to the transplant and had an undetectable viral load, and her post-transplant course was complicated by grade II GVHD that was treatment responsive. At the time of the report, 39 months post-transplant, the patient remained in remission and with undetectable HIV-1 viral loads.

The pattern of immune recovery following allogeneic stem-cell infusion remains incompletely understood, but case reports suggest that the CD4$^+$ lymphoid compartment does have some capacity to recover in HIV-1 patients post-HSCT [32]. The outcome in two HIV-infected recipients of reduced-intensity conditioning (RIC) for allo-HSCT demonstrated that reconstitution of tCD4$^+$ T cells was similar to that observed in other non-myeloablative transplants in HIV-1-negative recipients [37]. Of note, the HIV-1 naïve donor cells developed that ability to target HIV-1 epitope specificities that were different from pre-transplant patterns of the recipient. In this patient, who achieved full donor chimerism, there was also loss of detectable HIV-1 proviral DNA. This may be suggestive that the pool of latently infected lymphocytes was eliminated after transplantation, a phenomenon not seen in the autologous transplant patients [38]. Adding to this suggestive but anecdotal data is a series from Ohio State University that showed that all HIV-1-infected allogeneic HSCT recipients of RIC remained alive, in remission, off immunosuppression but on cART, at the follow-up time of 1 year [39]. Two of these patients remained HIV-1 RNA negative by clinical PCR assay. The first systematic study of the HIV-1 reservoir in the setting of RIC for allo-HSCT in HIV-1-infected recipients was recently reported by Henrich et al. [3]. Here, surrogate markers for the HIV-1 reservoir size, namely ultrasensitive PCR assays for HIV-1 RNA and DNA, HIV-1 tropism assays, and HIV-1 antibody were followed for up to 3.5 years while the recipients were continuously on cART. HIV-1 was undetectable by virus outgrowth assay, and RNA and DNA were negative in peripheral blood mononuclear cells (PBMCs), CD4$^+$ T cells, and plasma. Simultaneously with immune recovery and GVHD, the HIV-1 antibody decreased and, with the inability to detect HIV-1, there was the suggestion that under the cover of cART, the procedure was associated with a reduction in the HIV-1 reservoir [3]. These patients were taken off cART without a rebound in HIV-1 RNA (oral report, 2013 International AIDS Society Meeting, Kuala Lumpur). An ongoing study of allogeneic HSCT for treatment of hematologic malignancies by the Blood and Marrow Clinical Trials Network (NCT01410344) should resolve the question of whether an allogeneic HSCT can eliminate the HIV-1 reservoir and could be a curative strategy.

An alternative allogeneic approach is the use of cord blood HSCT-cb that has been screened for HIV-1 resistance factors [40,41]. It is estimated that there are as many as 400,000 cord blood units worldwide [40], and this could be developed as a donor source for this population. There is a small cord blood bank of CCR5-Δ32/Δ32 units, and these have been proposed as an alternative to matched unrelated donor transplants for AIDS-related hematologic malignancies; however, the statistical probability of finding a suitable match within such a cord blood bank is limiting [41]. The delayed immune recovery post-conventional HSCT-cb may also be problematic, but there is as yet no adequate experience in AIDS patients.

Autologous stem-cell transplantation in the AIDS patient with lymphoma

AIDS-related lymphoma

Although the era of cART has improved overall AIDS patient survival [42], cancers remain a continuing concern as a source of mortality [43]. In recent times, there has been a decrease in AIDS-defining cancers such as non-Hodgkin lymphoma (NHL) and a rise in HIV-1-related Hodgkin lymphoma (HL) [44]. Diffuse large cell lymphoma and Burkitt lymphoma are similar to those of HIV-negative patients, but plasmablastic and primary effusion lymphoma are more unique to HIV-1 infection.

The treatment of AIDS-related lymphomas changed after the introduction of cART, and what was once the standard approach using low-dose chemotherapy was supplanted by more aggressive therapies used in HIV-negative patients, such as R-CHOP [rituximab, cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), prednisone] for HIV NHL and ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine) for HL. HIV-1 response to cART is associated with improved survival following lymphoma treatment [45], with remission rates after R-CHOP approaching rates seen in HIV-negative lymphoma patients [46]. Recent studies found that short-course R-EPOCH [rituximab, etoposide, prednisone, vincristine (Oncovin), doxorubicin hydrochloride] gave a 5-year progression-free survival (PFS) and overall survival (OS) of 84 and 68%, respectively [47]. The National Cancer Institute (NCI) pioneered an approach of short-course R-EPOCH that attempted to achieve the goal of antilymphoma efficacy while preserving immune function [47]. In this paradigm, starting after two cycles of R-EPOCH, patients were restaged with computed tomography (CT) and [^{18}F[fluorodeoxyglucose positron emission tomography (FDG PET) scans after each cycle until they achieved a complete remission or stable disease. The minimum number of cycles administered was three, and side effects of chemotherapy were generally similar to those seen in HIV-1-negative lymphoma patients. Mixed opinion persists about whether to suspend cART during chemotherapy due to concerns that pharmacodynamic or pharmacokinetic drug–drug interactions could lead to more toxicity or to varying levels of antiviral drug levels that could induce HIV-1 resistance.

Salvage therapy for AIDS-related lymphoma using autologous HSCT

Autologous stem-cell transplantation (ASCT) in HIV-1-positive patients was initially reported in the pre-cART era [48]. In this case study, a 40-year-old male with HIV-1 infection and relapsed NHL was treated with the standard high-dose conditioning BEAM [BCNU (carmustine), etoposide, cytosine arabinoside (cytarabine), melphalan] and autologous HSCT while on zidovudine and zalcitabine antiretroviral therapy. The post-transplant course was complicated by multiple opportunistic infections, including cytomegalovirus viremia, mycobacterium pneumonia and cryptosporidiosis, underscoring the risk that AIDS-related immune dysfunction conferred. Nonetheless, it also demonstrated the feasibility of mobilizing stem cells and successful engraftment in the bone marrow milieu of active viral replication. This effort was followed by a larger French study of autologous transplantation that included AIDS patients with refractory or relapsed lymphoma, generally with undetectable HIV-1 plasma levels at study entry on cART [49]. Using conditioning regimens consisting of either radiation plus chemotherapy or chemotherapy alone, four of eight were alive and in complete remission at the time of reporting, three died of lymphoma within 3 months post-ASCT, and one died of a late opportunistic infection.

The City of Hope experience included patients with less advanced lymphoma and specifically excluded chemotherapy-refractory patients, similar to the institutional practice with HIV-negative patients [50]. The initial series of 20 patients with either HL or NHL were required to have HIV-1 viral levels in plasma <10,000 gc/mL on cART, and the majority of patients received high-dose conditioning chemotherapy consisting of CBV [cyclophosphamide, BCNU (carmustine), etoposide]. Engraftment times were similar to those with HIV-1 negative patients, except for one patient who had delayed engraftment until day 23. This patient engrafted after the discontinuation of the zidovudine component of the cART. Attempts were made to continue cART throughout the transplant period, but in reality 11 of 20 patients were unable to tolerate these oral medications because of nausea or mucositis. PFS and OS were superior to those in the French series (85 and 81%, respectively), likely due to the inclusion of only chemosensitive patients. The cohort was expanded to 29 patients and with a median of 41 months follow-up, the PFS remained high at 78% [51] (Figure 65.1). The 2-year disease-free survival (DFS) and OS were also similar [75% and 75% in the HIV-1-infected group versus 56% (p = NS) and 75%, respectively, in the HIV-negative group]. The non-relapse-related mortality was also similar between the groups at 11% [95% confidence interval (CI) 4–28%] in the HIV-1 positive patients versus 4% (95% CI 1–25%) in HIV-negative controls. Infectious complications did differ between the groups, with more opportunistic infections in the HIV-positive patients without impacting OS.

A retrospective case–control study comparing 53 HIV-1-infected lymphoma patients with 53 HIV-1-negative controls matched for histology, non-age-adjusted International Prognostic Index (IPI), and disease status at the time of transplant demonstrated the minimum effect of HIV-1 infection on outcome [52]. OS was 61.5% (95% CI 47–76%) for HIV-1-positive patients and 70% for controls (p = NS). There was a trend towards delayed platelet engraftment in the HIV-1 cohort. Similarly, a non-statistically significant difference in non-relapse mortality was seen in the HIV-1-infected cohort, primarily due to the higher rate of bacterial infections. Interestingly, although there was no difference in relapse rates between groups, there was a favorable tendency for lower rates in the HIV lymphoma group, similar to the City of Hope case–control series.

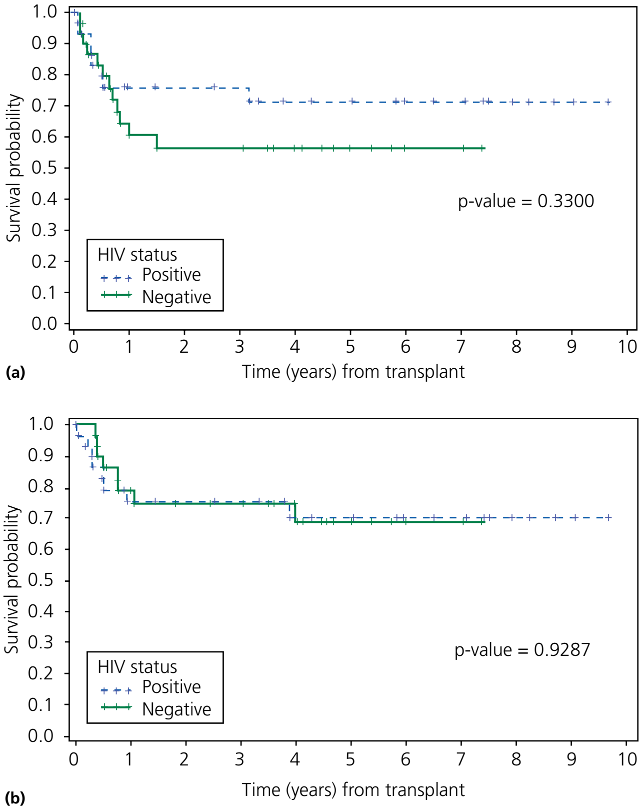

Figure 65.1 Probability of disease-free survival (a) or overall survival (b) by HIV-1 status (solid line, HIV-negative; dashed line, HIV-1 positive) in patients with non-Hodgkin lymphoma treated with dose-intense therapy followed by autologous HSCT. Source: Krishnan et al. 2010 [51]. Reproduced with permission of Elsevier.

The Italian Cooperative Group on AIDS and Tumors (GICAT) reported their long-term results on 50 patients with HIV-1 infection and relapsed/refractory NHL or HL [53]. Forty-six patients were already on cART and four started cART at the time of study enrollment or stem-cell mobilization. In contrast to the City of Hope requirements, any HIV-1 plasma RNA level was allowed, and viral loads at study entry ranged from 204,000 to 750,000 gc/mL. Thirteen patients were withdrawn before stem-cell collection due to toxic death (n = 2), progressive disease (n = 10), or patient refusal (n = 1). Of the remaining 37 patients, 31 adequately mobilized sufficient CD34$^+$ cells after either debulking chemotherapy (n = 19) or cyclophosphamide (4 g/m^2) + GCSF (n = 12). Ultimately, after early disease progression in four patients, 27 of the initial 50 patients underwent autologous HSCT after BEAM chemotherapy, and all engrafted at a median time of 10 days post-ASCT. The 3-year PFS for these patients was 76.3% [53], similar to the City of Hope experience. Multivariate analysis for prognostic factors for survival showed that marrow involvement, performance status <2, and CD4 count <100 cells/μL were significantly associated with poor outcome.

An EBMT retrospective multicenter experience with 68 patients from 20 institutions reported outcome with autologous HSCT involving high-risk patients in first CR (n = 16), with relapsed disease (n = 44), or chemorefractory disease (n = 8) [54]. Relapse or progression post-autologous HSCT occurred in 29.5% of patients, and transplant-related mortality was 7.5%, mainly due to bacterial infections. PFS was 56% , and analysis of prognostic factors demonstrated that histology, other than diffuse large-cell lymphoma, the use of more than two pretreatment regimens, and not being in clinical remission at the time of transplant were significantly associated with a higher risk of post-HSCT relapse [54]. Table 65.1 summarizes published outcomes of autologous HSCT for HIV lymphoma.

Given the favorable outcome of such salvage therapy in AIDS lymphoma, the question is whether the myeloablative conditioning affects the HIV-1 reservoir. To address this, Cillo et al. reported a retrospective analysis of frozen PBMC specimens from transplant survivors who remained on cART with no detectible HIV-1 RNA in plasma [38]. Specimens of blood, studied pre-transplant and at one other post-transplant time point, used assays for HIV RNA and DNA having single-copy sensitivity, a surrogate measure of the HIV-1 reservoir. Despite the absence of detectable HIV-1 RNA in plasma by routine assays, with the more sensitive assay 9/10 patients were viremic post-transplant while on cART, with a range of <0.15 to 26 HIV-1 genome copies/mL, and 9/10 were found to have detectable HIV-1 DNA. The stem-cell infusion product undoubtedly was contaminated by HIV-1-infected cells, and the transplant recipients were likely "re-infected" with endogenous virus post-transplant, perhaps during the cessation of cART. Nevertheless, there was no suggestion that myeloablative chemotherapy followed by cART had any substantive effects on the HIV-1 reservoir. Based on this, it could be concluded that the method used was not sufficient for eliminating HIV-1 infection.

Table 65.1 Outcome of autologous HSCT in high-risk AIDS lymphoma

Ref.	No. of patients	Conditioning regimen	PFS (%)	Median time to follow-up
Gabarre et al. 2004 [92]	14	BEAM/CY TBI/ other	29	49 months
Krishnan et al. 2005 [58]	29	CY/VP16/TBI CBV	76	24 months
Spitzer et al. 2008 [93]	20	BU/CY	50	23 weeks
Re et al. 2009 [53]	27	BEAM	76	24 months
Balsalobre et al. 2009 [54]	68	BEAM and variants	56	32 months

BEAM, BCNU (carmustine), etoposide, cytosine arabinoside (cytarabine), melphalan; BU, busulfan; CBV, cyclophosphamide, BCNU (carmustine), VP-16 (etoposide); CY, cyclophosphamide; CBV, cyclophosphamide, BCNU (carmutine), VP-16 (etoposide); TBI, total body irradiation.

Management of the AIDS patient during HSCT

Conditioning for allogeneic HSCT in hematologic malignancy

A variety of conditioning regimens have been used in the setting of HSCT for HIV-1 malignancy, and these are in general the same as those used in the non-HIV-1-infected population [32]. Even the use of antithymocyte globulin is tolerated in the HIV-1-infected patient [55]. Most of the differences in management of the HIV-1-infected patient undergoing HSCT occur during conditioning and are related to the antiretroviral therapy. In the now famous "Berlin" case of allogeneic transplant from a CCR5-Δ32/Δ32 matched unrelated donor, a fully ablative conditioning regimen was used consisting of amsacrin, fludarabine, and cytarabine for the first transplant and, following relapse, cyclophosphamide and TBI for the second [2].

Conditioning for autologous HSCT in hematologic malignancy

The City of Hope experience with autologous stem-cell transplantation for lymphoma utilized either CBV or FTBI (full total body irradiation) plus cyclophosphamide and etoposide for conditioning. As noted above, this case–control analysis compared HIV-1-negative and -positive patients with lymphoma and did not show any difference in transplant-related mortality between groups [51]. Other trials involving autologous transplant for HIV lymphoma have used BEAM- or FTBI-based regimens [53,54]. A large ongoing intergroup BMT CTN (Blood and Marrow Transplant Clinical Trials Network)-sponsored trial of autologous HSCT in AIDS-related NHL used BEAM, which is becoming the preferred conditioning regimen for this disease.

cART management during HSCT

The use of antiretroviral therapy in the HSCT setting is not different to that in the solid organ transplant setting. In solid organ transplantation, the major challenge is managing the drug interaction between antiretroviral drugs and immunosuppressive agents. Ritonovir-boost protease inhibitors are particularly problematic to administer during the HSCT conditioning regimen and post-transplant period due to extensive drug–drug interactions. Indeed, in one of the first case reports of a liver transplant, the patient developed toxic levels of cyclosporine due to its interaction with cART [56]. In the HSCT setting, there is the added concern of interaction between cART and the chemotherapy used for conditioning or for GVHD prophylaxis. Hence there must be a balance in management of the HIV/AIDS patient during HSCT; on the one hand, the cART must not negatively impact the required drugs needed for the transplant procedure, and on the other, the cART must be available to prevent any rebound in HIV-1 infection that might affect the outcome of the transplant. However, for practical reasons, oral cART is often interrupted due to patient intolerance from mucositis or GVHD. At present, subcutaneously administered enfuvirtide is the only parenteral anti-HIV-1 agent available, and use of this agent should be considered in the design of the cART regimen. The goal should be to minimize the cessation of cART since HIV-1 rebound can lead to infection that can affect the allogeneic graft, as shown in a study by Kang et al. in which a patient developed an acute febrile illness and a rise in HIV-1 viral load to 1,000,000 gc/mL [57]. The autologous HSCT recipient receiving myeloablative conditioning with CBV or TBI is more likely to be intolerant of cART early post-transplant and may not resume medication for 1–2 months post-transplant. Despite this, few long-term problems with HIV-1 drug resistance or with CD4 count recovery are seen [58]. However, BEAM conditioning has shown less oral medication intolerance and ability to continue cART during the early transplant period due to chemotherapy-related side effects [53]. Based on this and the emerging data on the potential effect of continued cART on the HIV reservoir, as seen in the allogeneic transplant setting [3], the current recommendation is to maintain strict adherence to cART coverage during either autologous or allogeneic transplant. This may require substitution of cART with the parenteral agent enfuvirtide in some patients.

The main clinical concern with cART management of the AIDS patient undergoing HSCT is drug–drug interactions. Although there is limited information in this area, case reports have provided information regarding the effect on the cytochrome p450 system to guide current therapy [32]. As shown in Table 65.2, recommendations from ongoing BMT CTN trial 0903 suggest modification of certain cART regimens prior to the conditioning period. As summarized here, for fludarabine/busulfan and fludarabine/melphalan regimens, for which liver metabolism occurs, both raltegravir-based integrase strand transfer inhibitor (INSTI) therapy and non-nucleoside reverse transcriptase inhibitor (NNRTI)-based cART may be continued as tolerated. However, ritonavir-boosted protease inhibitor (PI)-based cART requires a period of brief cART cessation or modification. Ritonavir strongly inhibits CYP3A4 activity [59], and this should increase busulfan levels. It is recommended, therefore, to remove ritonavir and substitute another agent, usually raltegravir, in the cART regimen. For cyclophosphamide-based conditioning regimens and GVHD prophylactic regimens that utilize post-transplant cyclophosphamide, the ritonavir-induced inhibition of CYP3A4 will likely lower the active metabolites of cyclophosphamide and potentially reduce the intended cytoreductive effect. However, NNRTI drugs induce CYP3A4 activity and should have the opposite effect on levels of active metabolites of cyclophosphamide. Until definitive studies are available, it is recommended to substitute for any ritonavir-boosted cART regimen and to use NNRTI-based cART with caution.

Fungal and GVHD prophylaxis in the HIV/AIDS patient after HSCT

Because of the complex interactions of the triazoles (voriconazole, itraconazole, and to a lesser extent posaconazole) with both cART and with tacrolimus/rapamycin regimens, the echinocandins (anidulafungin, caspofungin, micafungin) and amphotericin B are preferred for antifungal prophylaxis. In addition, the immunosuppressive medications used for GVHD prophylaxis must be managed

Table 65.2 Recommendations for cART use during conditioning regimen[a],[b]

Conditioning regimen	Metabolism (primary site)	Interaction potential [strength of evidence]	Recommendation
Flu/Bu • Fludarabine • Busulfan	Fludarabine (liver): • Rapid dephosphorylation to 2-fluoro-Ara-A, then phosphorylated to 2-fluoro-Ara-ATP intracellularly Busulfan (liver): • Metabolized hepatically; substrate of CYP3A4	High Concomitant administration of ritonavir-boosted PIs may increase the levels of busulfan. [Strength of evidence: LOW]	Raltegravir-based: may continue cART as tolerated NNRTI-based: may continue cART as tolerated PI-based: regimens including ritonavir should be discontinued a minimum of 48 hours prior to the administration of myeloablative regimens containing busulfan Antiretroviral therapy should not be resumed until, at least, 48 hours after the last dose of busulfan and once the patient is able to tolerate oral medications consistently
Flu/Mel • Fludarabine • Melphalan	Fludarabine (liver): • Rapid dephosphorylation to 2-fluoro-Ara-A, then phosphorylated to 2-fluoro-Ara-ATP intracellularly Melphalan (blood): • Chemical hydrolysis in the plasma to inactivate metabolites	Low The effects of ritonavir-boosted PIs on levels of fludarabine are unknown Efavirenz has been given in combination with fludarabine [Strength of evidence: MODERATE]	Raltegravir-based: may continue cART as tolerated NNRTI-based: may continue cART as tolerated PI-based: the potential for interactions with ritonavir-boosted PIs or NNRTIs is low. Antiretroviral therapy can be continued if the benefits clearly outweigh the risks
Cy/TBI • Cyclophosphamide • TBI	Cyclophosphamide (liver): Prodrug is converted by hepatic microsomal enzymes to the active form. The activation pathway involves CYP3A4 isoenzymes. • Substrate for CYP2A6 (minor), 3A4 (major) • Inhibits CYP3A4 (weak) • Induces CYP2B6 (weak), 2C8/9 (weak) Active metabolites include acrolein	High Complex interactions exist between ritonavir and cyclophosphamide or its metabolite, acrolein. Cyclophosphamide levels may be increased when combined with protease inhibitors, but the active metabolites may be decreased NNRTIs may increase levels of acrolein through CYP induction if similar to other CYP inducers such as phenytoin that can increase the AUC of active metabolites by 50% [Strength of evidence: LOW]	Raltegravir-based: may continue cART as tolerated NNRTI-based: regimens including NNRTIs should be used with caution and with frequent monitoring due to the increase in toxic metabolites caused by CYP450 induction PI-based: regimens including ritonavir should be discontinued a minimum of 48 hours prior to the administration of myeloablative regimens containing cyclophosphamide Antiretroviral therapy should not be resumed until, at least, 72 hours after the last dose of cyclophosphamide and once the patient is able to tolerate oral medications consistently

[a] cART combinations may not have been studied but the interaction potential has been predicted based on the metabolic pathways of the various agents.

[b] Recommendations summarized from the Bone Marrow Transplantation Clinical Trials Network protocol 0903, with permission.

differently in the setting of cART. Again, the potent inhibition of CYP3A4 by ritonavir will increase both tacrolimus and sirolimus blood levels. The NNRTI-based cART regimens have the opposite effect of reduced tacrolimus and sirolimus levels due to induction of CYP3A4, and this is especially true for efavirenz and nevirapine. Since many patients are unable to take the cART as oral medication during the acute transplant phase, when cART is reintroduced patients are already on an immunosuppressive regimen. As noted in Table 65.3, the immunosuppressant dose may need to be adjusted based on trough levels after the reinitiation of cART. To complicate the dosing further, sometimes the full induction of CYP3 A4 may take several weeks, hence the full extent of the cART effects may not be seen immediately. It should additionally be noted that dose adjustments based on drug toxicity may also be complicated by difficulty in accurately identifying the suspect agents. For example, patients on tenofovir may experience renal toxicity, a side effect also seen with tacrolimus. If patients have impaired renal function, in addition to reducing the immunosuppressant doses, one has to remember that nucleoside reverse transcriptase inhibitors (NRTIs) are usually excreted renally, and hence also may need dose adjustment. Good clinical judgment and availability of drug levels are essential in optimizing patient management.

Gene therapy for HIV/AIDS

The rationale of an HSCT-based strategy for HIV/AIDS is the generation of a new immune system that would control HIV-1 infection while at the same time destroying the endogenous reservoir of virus, leading to a cure of the infection. Success would be largely predicated upon the creation of a durable (HIV-1 resistant) immune system through transplantation of resistant HSPCs [60]. Approaches have used xenogeneic, allogeneic, and autologous blood stem cells. A single unpublished case of a baboon stem-cell transplant into an HIV-1-infected patient occurred in 1995, but no further attempts at xenogeneic treatment of HIV-1 are known. The feasibility of transferring HIV-1 resistance via HSPCs was best demonstrated when an AIDS patient with acute myeloid leukemia was transplanted with HLA-matched, unrelated donor HSPCs containing a homozygous 32-base pair deletion in the chemokine receptor 5 gene (CCR5Δ32/Δ32) [2]. Individuals who are homozygous at this locus do not express CCR5 on their cell surface, and therefore cannot be infected with CCR5 (R5) tropic HIV-1 [61]. The recipient attained complete hematopoietic reconstitution with the donor graft, suspended cART early after HSCT, and remained with undetectable HIV-1 RNA in blood and undetectable HIV-1 DNA in tissues using single-copy sensitive PCR methods for more than 5 years after treatment [62]. As noted above, the allogeneic effect itself could explain the favorable outcome in this case, but the use of mutant donor cells implies some potential contribution of cellular resistance to infection. Despite the success of this single case, the statistical improbability of a donor having both the homozygous CCR5Δ32/Δ32 mutation and HLA compatibility severely limits this approach. The frequency of homozygous CCR5Δ32/Δ32 genotype is <2% in the Western European Caucasian population and virtually absent in people of Asian and African descent [63]. Hence genetic modification of autologous HSPCs is addressed in an effort to create an alternative strategy.

Table 65.3 Guidance for dosing of tacrolimus and sirolimus during cART[a]

Concomitant medication	Effect on tacrolimus dosing	Effect on sirolimus dosing
Protease inhibitors [r = boosted]: • Atazanavir/ritonavir [ATZ/r] • Fosamprenavir/ritonavir [fAPV/r] • Indinavir/ritonavir [IND/r] • Lopinavir/irtonavir [LPV/r] • Saquinavir/ritonavir [SQV/r] • Tipranavir/ritonavir [TPV/r] • Atazanavir [ATZ] • Nelfinavir [NFV]	↑↑↑ Tacrolimus levels due to potent inhibition of CYp3A4 and P-glycoprotein, especially with ritonavir-boosted cART regimens [94,95] **Hold drug**; Target tacrolimus trough = 5–15 ng/mL Dose base on daily trough: <5 ng/mL: 1 mg PO or 0.25 mg IV 5–15 ng/mL: 0.5 mg PO or 0.125 mg IV >15 ng/mL: Hold tacrolimus until next level	↑↑↑ Sirolimus levels due to potent inhibition of CYP3A4 and P-glycoprotein, especially with ritonavir-boosted cART regimens [96] **Hold drug**; Target tacrolimus trough = 3–12 ng/mL Dose base on daily trough: <3 ng/mL: 0.4 mg PO 3–12 ng/mL: 0.3 mg PO >12 ng/mL: Hold sirolimus until next level
Non-nucleoside RT inhibitors: • Efavirenz [EFV] • Nevirapine [NVP] • Etravirine [ETV]	↓ Tacrolimus levels due to induction of CYp3A4 [94] **Continue drug**; Target trough = 5–15 ng/mL Avoid use with ETV; for EFV and NVP base daily tacrolimus dose on trough[c]: <5 ng/mL: increase dose by 25%[c] 5–15 ng/mL: no adjustment >15 ng/mL: decrease dose by 25%	↓ Sirolimus levels due to strong induction of CYp3A4[b] **Continue drug**; Target trough = 3–12 ng/mL Avoid use with ETV; for EFV and NVP base daily sirolimus dose on trough[c]: <3 ng/mL; increase dose by 25% 3–12 ng/mL: no adjustment >12 ng/mL: decrease dose by 25%
Nucleoside RT inhibitors: • Abacavir [ABC] • Didanosine [ddI] • Emtricitabine [FTC] • Lamivudine [3TC] • Stavudine [d4T] • Tenofovir [TDF] • Zidovudine [AZT, ZDV]	No effect known [97] No dose adjustment necessary but monitor tacrolimus trough 2–3 times per week Monitor renal function for patients on TDF[d]	No effect known No dose adjustment necessary but monitor sirolimus trough 2–3 times per week Monitor renal function for patients on TDF[d]
Integrase inhibitor: • Raltegravir [RLV]	No effect known[e] No dose adjustment necessary	No effect known[e] No dose adjustment necessary
Fusion inhibitor: • Enfuvirtide [ENF, T20]	No effect known[f] No dose adjustment necessary	No effect known No dose adjustment necessary
CCR5 antagonist: • Maraviroc [MVC]	No effect known No dose adjustment necessary	No effect known No dose adjustment necessary

[a] Based on information provided in Bone Marrow Transplantation Clinical Trials Network protocol 0903, with permission; recommendations may be based on known or theoretic effect of antiretroviral agent or class of retroviral agent on cytochrome P450 enzymes or P-glycoprotein 1.
[b] EFV is more potent than NVP as an inducer of CYP3A4; full induction can take up to 2 weeks.
[c] Recommendation based on theoretical considerations of the potent induction of CYP3A4 by ETV.
[d] For patients with renal impairment, adjust nucleoside RT inhibitor dose based on agent package information.
[e] Raltegravir-based regimens may be preferred over PI- or NNRTI-based regimens since metabolism is by glucuronidation and not by CYP3A4 metabolism.
[f] Enfuvirtide is administered subcutaneously and may be used at times when patients cannot take oral medications.

Molecular basis for gene therapy of HIV/AIDS

Gene-based strategies target viral or cellular elements necessary to suppress HIV-1 infection, to protect CD4⁺ T cells and other susceptible cells from further HIV-1 infection, and to restore immune function [4]. Gene therapy involves the transfer of genetic information (transgene) into human subjects to replace a missing or defective function or to produce an intracellular molecule (RNA, DNA, protein) for therapeutic purposes. Highlighted here are those strategies undergoing clinical evaluation and those in advanced preclinical development (Tables 65.4 and 65.5). Among genetic strategies are cell- and gene-based therapeutic approaches that can be used in concert with conventional antiretroviral drugs. This approach was made possible by the ability to copy human genes in vitro and then insert them into target cells of interest. Although simple at first glance, this process is highly complex.

First, the transgene must be cloned into a delivery vehicle (vector) that also provides the transcriptional regulatory elements required for gene expression. The delivery vehicle may be a viral or non-viral vector. Second, the vector must be delivered efficiently into the target cells. Most delivery methods employ a process whereby cells are removed from the patient, and the transgene is delivered to the target cells ex vivo. The modified cells are then expanded in culture and reinfused into the patient. Several approaches for direct delivery of genes to target cells in vivo, bypassing the need for expensive time-consuming ex vivo cell manipulations, are also in clinical studies, but at this point these are restricted to local tissue delivery such as skin, muscle, or lung. Third, except for strategies that edit the genome by transient exposure to nucleases, most strategies require long-term stable expression of the transgene in modified cells.

Both integrating and non-integrating vectors are being developed, with each having their own unique advantages and disadvantages [4,64]. Vectors that can integrate the transgene into host DNA promise to produce long-lived expression, whereas non-integrating vectors can be expected to have a shorter period of expression but will minimize the theoretical risk of insertional mutagenesis by the integrated DNA. Efforts to improve the technologies are directed towards the three critical problems facing this approach: the design of better strategies for efficient, safe, and cost-effective gene delivery, the design of new molecular targets for improved antiviral effect, and the development of clinical trials that test the feasibility and safety of these approaches. These three aspects of gene therapy for HIV-1 infection are described below, but for a more complete discussion the reader is referred to specific reviews of the field [64,65].

Molecular strategies for HIV-1 gene therapy

A diverse array of transgenes to suppress HIV-1 functions or block the infectious cycle have been designed and several of these have been tested in vivo (see Table 65.4). These can be broadly categorized into two groups: those coding for nucleic acid-based suppressors and those coding for protein-based suppressors. As in drug-based therapy, the rationale for antiviral gene therapy is that

Table 65.4 Anti-HIV gene therapeutics in clinical trials

Mechanism of antiviral	Target	Delivery of genes/cell transplantation	Sponsor	Phase	Status of trial	Ref.

inhibition of the virus at several critical steps of virus replication is likely to result in a more complete and effective suppression than a blockade at a single step of virus infection. Also, as in drug-based therapy, concerns for emergence of HIV-1 variants that resist or escape the gene-based strategy apply. For these reasons, current gene therapy strategies use combinations of different types of transgenes with different viral and cellular targets that aim to neutralize completely HIV-1 functions at different points in the infection cycle. The several genetic inhibitor strategies that have entered clinical trials are outlined in Table 65.4.

RNA-based suppressors

The binding of newly transcribed RNA-antisense molecules to mRNA sequences prevents translation of the encoded protein, thereby resulting in loss of gene function. The first lentivirus vector-based gene transfer in humans encoded an antisense to HIV-1 *env*, in the setting of T-cell immunotherapy, and was shown to be safe [66]. RNA decoy strategies attempt to compete with specific HIV-1 RNA elements that bind viral proteins as part of the replication cycle by overexpressing their RNA homologs. TAR (Tat response element) and RRE (Rev response element) are two such *cis*-acting factors that are necessary for proper function of the key HIV-1 regulatory proteins, Tat and Rev. Together, these and related studies provided the conceptual basis for a clinical trial of transduced and transplanted marrow-derived HSC in HIV-1-infected children [67].

Ribozymes are RNA molecules that can cleave RNA targets at specific sequences, a property that is being exploited to cleave and thus inactivate HIV-1 RNAs [64]. The first in vitro study suggesting the use of a "hammerhead" ribozyme to suppress HIV-1 was directed against the HIV-1 *gag* RNA sequence [68]. A "hairpin" ribozyme that cleaved at the leader sequence at the 5′ end of the HIV-1 genome conferred resistance to several HIV-1 isolates and considerable inhibitory activity was observed for up to 35 days in vitro [69]. Clinical trials using ribozymes, used as a component of combinatorial gene therapy, are currently active [70].

RNA interference (RNAi) is based on a cellular process in which double-stranded RNA (dsRNA) induces a post-transcriptional degradation of homologous transcripts, and RNAi has been observed in a variety of organisms including fungi, plants, insects, protozoans, and mammals [71]. RNAi is initiated by exposing cells to dsRNA via either transfection or endogenous expression of viral or transposon RNAs. dsRNAs is processed by the RNAse III-like enzyme, called "dicer," into 21–23 nucleotide double-stranded fragments known as short interfering RNAs (siRNAs). These siRNAs form a complex known as the RNAi-induced silencing complex (RISC), which leads to cognate target RNA destruction. Chemically synthesized 21–23 length siRNA nucleotide duplexes with short 3′ overhangs have been synthesized and are capable of mediating RNAi in vivo and in vitro. Several studies have demonstrated that the functional unit of RNAi, the siRNAs, can elicit sequence-specific target downregulation either by introduction of preformed siRNAs via transfection or by endogenous expression of 21–23 base-paired RNAs using polymerase III promoter systems [72]. This enabling of expression of siRNAs in mammalian cells has opened up new possibilities for therapeutic applications of siRNAs.

RNAi can be applied as a potent mechanism for inhibition of HIV-1 infection and represents a potentially powerful tool for anti-HIV therapy [73]. The recent publications demonstrating that HIV replication can be inhibited by using either synthetic or expressed siRNAs, targeting the virus, its receptor, or its coreceptor, have generated a great amount of interest and enthusiasm for further testing of the anti-HIV therapeutic potential of siRNAs. There are at least two different modalities by which siRNA can be used as an antiviral: transfection of the preformed siRNAs or intracellular expression of siRNAs. The latter approach has been utilized in a gene therapy setting, providing anti-HIV-1 RNAs to hematopoietic cells susceptible to HIV-1 infection [70].

Protein-based suppressors

Transdominant mutant proteins act as competitors of cognate HIV-1 proteins and thus suppress normal viral functions. The most experimentally advanced transdominant protein to date is a mutant Rev protein (RevM10) [74]. RevM10 retains two Rev functions: the ability to bind RRE on the viral genome and the ability to form Rev multimers. However, RevM10 is incapable of exerting its regulatory role in transporting unspliced or singly spliced RNAs from the nucleus to the cytoplasm. Hence susceptible cell lines that express RevM10 exhibit long-term (>30 days) resistance to HIV-1 replication and human CD34$^+$ blood progenitor cells, transduced with RevM10, can give rise to T-lymphocytes that exhibit significant resistance to challenge with HIV-1. A RevM10-based gene therapy strategy used in association with allogeneic HSCT has been described [57].

Clinical trials of gene therapy for HIV-1 infection

The first clinical gene therapy study in HIV-1 infected humans examined the potential of RevM10 to prolong the survival of transduced CD4$^+$ T cells in vivo [75]. In this study, the duration of engraftment was limited and transient, but a subsequent study, using a retrovirus delivery vector in lieu of plasmid DNA, achieved improved survival in T cells expressing the RevM10 compared with T cells transduced with a negative control vector [76].

Strategies based on preventing the expression of chemokine coreceptors at the cell surface are particularly attractive primarily because they block the very first step in HIV-1 infection of target cells rather than blocking a viral event that occurs after the establishment of the proviral DNA in the cellular genome. Such chemokine-modified cells should also have survival advantages in vivo in HIV-1-infected individuals, suggesting a potential for selection of resistant T cells during infection with R5 virus [77]. Moreover, a gene-based approach that utilizes a human protein is more likely to induce an immune response against the expressed protein, an undesired outcome that could lead to clearance of transduced cells by the immune system. Because HIV-1 replication can be influenced by a variety of cellular perturbations, there are several other molecular strategies for inhibiting this virus (see Tables 65.4 and 65.5), and these strategies will likely increase as more becomes known about the biology of HIV-1.

Clinical trials of gene therapy using hematopoietic stem cells

Conceptually, HSPCs, transduced with potent anti-HIV-1 genes, should confer anti-HIV-1 protection to all susceptible hematopoietic cell lineages (e.g., CD4$^+$ T cells, monocytes, Langerhans cells, dendritic cells, and astrocytes) for the life of the infected individual. The key question then becomes: how does one develop a practical method to bring HSPC manipulation and transplantation to the target patient population? In the first genetic modification of allogeneic HSPCs, noted above, using RevM10 as the transgene a single recipient of a matched related HSPC was treated after receiving RIC [57]. This patient's course was complicated by grade II acute GVHD and by limited chronic GVHD, but she was alive and in complete remission at 3 years post-HSCT. [Note: this patient subsequently died of thrombotic thrombocytopenic purpura at 3.5 years post-HSCT, at which time her HIV-1 was undetectable on cART (J. Tisdale, personal communication)]. As noted above, ongoing experience suggests that the allogeneic effect itself could have produced an anti-HIV-1 effect, even without genetic manipulation of the stem cells [3]. Studies are in place to determine what role allogeneic HSCT might have in HIV cure strategies [3,4]. The population with AIDS-related hematologic malignancy forms a target group in which therapy with or without artificially induced HIV-1 resistance in donor cells could be tested as a curative strategy for HIV/AIDS.

Gene therapy with autologous HSPCs

Genetic modification of autologous HSPCs has been proposed as a strategy that could engraft HIV-1 resistance and would avoid any problem of GVHD. A large phase II trial of gene-modified autologous cell therapy, in the absence of conditioning therapy, has been reported [78]. This study demonstrated the use of cART interruption in trial design, but in the absence of pre-transplant conditioning there was only a minimal detection of gene-marked PBMCs and only a transient effect on HIV-1 levels. Nevertheless, this pioneering study demonstrated the novel use of cART analytical treatment interruption for testing the anti-HIV-1 efficacy of gene therapy.

The first use of a conditioning regimen in patients receiving autologous gene-modified stem cells was performed in the setting of salvage therapy of AIDS lymphoma [70]. The patients required autologous HSCT, and represent a population in which the potential for engraftment of gene-modified HSPCs could be evaluated. DiGiusto et al. reported this pilot clinical study in which such patients undergoing high-dose chemotherapy and autologous stem-cell transplantation were infused with combined gene-modified and non-modified HSPCs [70]. Four patients were treated with mobilized and selected CD34$^+$ HSPCs transduced with a lentivirus encoding three anti-HIV-1 RNAs, namely TAR, siRNA to tat/rev, and a ribozyme targeting CCR5 [79]. There were no serious adverse events attributable to the research HSPC product, and as shown in Figure 65.2, gene marking was present in all patients for varying periods post-HSCT. This pilot study demonstrated the safety and feasibility of the approach following myeloablative conditioning. Still, the level of marking was less than 0.35% of PBMCs, and studies continue using improved methods of gene delivery to improve this outcome.

A major limitation in use of autologous HSPC-based gene therapy is the requirement for engraftment of adequate numbers of stem cells to overcome the endogenous pool of cells. The use of autologous HSC for delivery of genetically modified stem cells for treatment of HIV/AIDS will require an optimized conditioning regimen, and this is still unknown. One must balance the need for safety with the need to engraft efficiently. For non-cancer populations, dose intensity is usually not ethically warranted, and one must seek an adequate non-myeloablative treatment regimen to ensure stem-cell engraftment. However, it has been suggested that if there is no selective advantage of the gene-modified cells, then non-myeloablative conditioning will ultimately fail [80]. Busulfan is considered non-myeloablative when used alone at <9 mg/kg total dose [81] and, recognizing that myeloablative doses of busulfan are not justified in the non-cancer setting of AIDS, what would be an appropriate non-myeloablative dosing regimen? Clinical trials in the correction of human genetic diseases using gene-modified HSPCs have provided direction with use of busulfan-based regimens [82], and these approaches are now being evaluated in the setting of HIV/AIDS. In this regard, in adenosine deaminase-deficient children, busulfan was first used at 2 mg/kg intravenously for 2 days followed by infusion of CD34$^+$-transduced bone marrow cells [83]. Later, Candotti et al. correlated busulfan dosing with area under the curve (AUC) measurements showing that at doses ranging from 65 to 90 mg/m^2 (equivalent to ~4 mg/kg), the achievement of AUC in the range 4000–4800 mUmin was associated with engraftment [84]. Patients had minimal symptoms but did have transient neutropenia, mild thrombocytopenia, and transient elevated liver enzymes. In another series of patients with X-linked chronic granulomatous disease (CGD), liposomal busulfan at 4 mg/kg/day for 2 days was used, and the absolute neutrophil count recovery occurred after 18–21 days [85]. For the ongoing trials in HIV-1 infected patients without malignancy, the early conditioning regimen of choice has been busulfan in dose escalation study design.

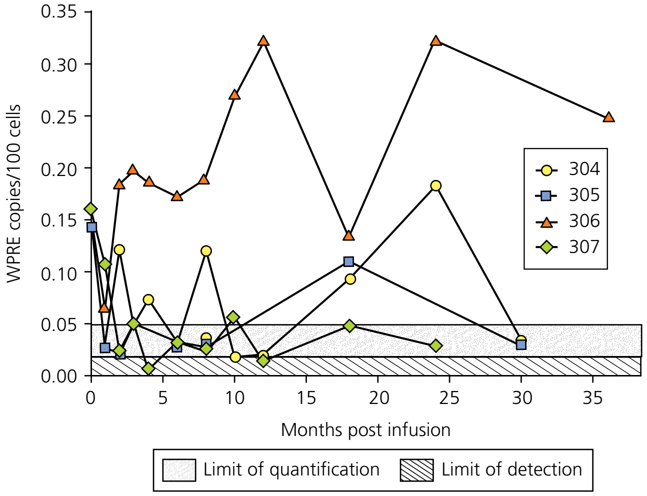

Figure 65.2 Gene marking in peripheral blood following autologous HSCT for AIDS-related lymphoma in four patients (Nos. 304–307). The number of copies of integrated vector per 100 peripheral blood leukocytes is shown over time.

Gene therapy using CD4$^+$ T cells

Use of autologous T-lymphocytes as the target cells for anti-HIV-1 gene modification of CD4$^+$ T cells represents another cell-based strategy for gene therapy [75]. A similar strategy, in which mature CD8$^+$ T cells were modified to kill HIV-infected cells, has also been reported [66]. In either case, mature T-lymphocytes have attributes that make them attractive targets for gene therapy: they are easily obtained from the donor's peripheral blood and they can be expanded to large numbers in vitro. Indeed, a method of cell expansion that involves cell surface stimulation, using antibodies to CD3 and CD28, promotes the expansion of cells to very high numbers [86]. Targeting mature T-lymphocytes for gene therapy has the added advantage that the effect of the therapeutic gene can be rapidly monitored for effects on cell survival, viral load, and other parameters. The transduced cells can also be selected in vitro, using the marker gene included in the vector, before reinfusion in the host, thereby generating a highly enriched population of genetically modified cells. For these reasons, gene therapy approaches that target mature lymphoid populations may be the method of choice for initial evaluation of new gene therapy strategies. Using a lentivirus vector to transfer an antisense RNA target to the HIV-1 envelope, CD4 lymphocytes have been safely infused into AIDS patients who were resistant to antiretroviral therapy [66]. More recently, it has been shown that the CCR5 gene can be edited using zinc finger nuclease (ZFN), and clinical trials are in progress [87].

Future directions of gene therapy for HIV/AIDS

The field of gene therapy is only beginning to demonstrate its potential, and one can only imagine how this will affect the management of patients in the future. Table 65.5 lists some recent discoveries that are likely in the next few years to reach clinical testing. Technology continues to address areas that are key for overcoming current limitations. Improved cellular processing is advancing our ability to manufacture efficiently genetically modified stem-cell products [65], and it is possible that these improvements will make stem-cell therapy available in ways that are affordable to HIV/AIDS patients. ZFN targeted to CCR5 [88], new multiplexed anti-HIV-1 combinations that include host restriction factors [89], and directed expression of neutralizing antibody [90] are new approaches to protection from HIV-1 infection. However,, for autologous therapy to be successful, there will likely need to be a method of selection of the genetically protected cell during HIV-1 infection. There is some expectation that HIV-1 itself could be used for selection [77], but chemical selection using methylguanine methyltransferase (MGMT) has been shown to protect macaques from infection [91].

MGMT-based selection has already been used in humans in cancer treatment, and this approach is moving rapidly to clinical testing in HIV/AIDS.

Conclusion

The application of HSPC technology to the treatment of HIV/AIDS is reaching a point at which clinicians are seeking curative strategies. It remains to be determined how HCT will supplement cART in the management of HIV-1-infected patients. Assuming that cell-based gene therapy will become optimized for safety, specific uses for gene therapy are likely to be identified and the test-of-concept for this approach could be established with a goal of decreasing or destroying the virus reservoir and blocking disease progression.

CHAPTER 66

Hematopoietic Cell Transplantation for Autoimmune Diseases

Richard A. Nash
Colorado Blood Cancer Institute, Presbyterian/St. Luke's Hospital, Denver, CO, USA

Introduction

An autoimmune disease is characterized by organ damage resulting from an immunologic response to self-antigens. Autoimmunity, on the other hand, is an immune response to self-antigens but without the implication that this has resulted in organ damage. Autoimmunity may be present spontaneously in normal individuals or after an infectious or other disease-related event which results in tissue damage (e.g., infarction). Criteria that support a disease having an autoimmune mechanism are (1) humoral or cellular self-reactivity, (2) disease-related autoantibody or lymphocytic infiltrate in pathologic lesion without other identified cause, and (3) autoantibodies or T cells that cause tissue pathology or cell dysfunction by transplacental transmission, adaptive transfer into animals, or in vitro experiments. An autoimmune disease develops in approximately 3–8% of the population [1]. Autoimmune diseases may involve single organs or multiple systems and may or may not have defined antigenic targets. Most autoimmune diseases are not life threatening and can be effectively treated even if they are not curable. However, some autoimmune diseases may be life threatening or damage critical organs and become refractory to conventional treatments. This, then, would be the candidate population for consideration of an approach requiring autologous or allogeneic hematopoietic cell transplantation (HCT).

Proposed mechanisms for autoimmunity and autoimmune diseases

To understand better how an approach using HCT might be effective for the treatment of an autoimmune disease, an understanding of the pathogenic mechanisms of autoimmune disease is required. There is a marked diversity of the B- and T-cell receptor specificity that results from somatic genome modification in lymphocytes. This allows for an effective immune response to foreign antigens. The unique specificities of these receptors are generated during B- and T-cell differentiation by recombination of the variable (V), diversity (D), and joining (J) genes and then later, in B cells, somatic hypermutation generates further diversity. These random processes of recombination and somatic hypermutation result in a significant percentage of lymphocytes (up to 50%) with B- and T-cell receptors that have an affinity for self-antigens [2].

It has been proposed that there are four cellular strategies to prevent the development of autoimmunity and autoimmune diseases from lymphocytes with self-reactive receptors. First, lymphocytes with high-affinity, self-reactive receptors can be clonally deleted. Clonal deletion occurs in central lymphoid organs during development. Second, a self-reactive receptor can be edited by further V(D)J recombination or somatic hypermutation to display a different receptor that is not self-reactive [3]. Receptor editing induced by self-reactivity can occur in both B and T cells. For B-cell receptor editing, new rearrangements at L chain loci and less commonly at H chain loci are induced. Third, downregulation of cell surface self-reactive receptors and intracellular changes, including those which affect signal pathways, decrease responsiveness to binding of self-reactive receptors, resulting in clonal anergy [4]. Last, extrinsic factors such as cytokine dependence for proliferation and regulatory mechanisms including regulatory T cells may limit the activity of lymphocytes with self-reactive receptors. In B cells with self-reactive receptors, B-cell-activating factor (BAFF) receptor is poorly induced and therefore may be more susceptible to competitive regulation by their requirement for BAFF than other B cells with non-self-reactive receptors.

Some T cells with self-reactive receptors are positively selected in the thymus after T-cell receptor engagement by self-peptide–major histocompatibility complex (MHC) class II complexes. They develop into $CD25^+CD4^+$ $FoxP3^+$ regulatory T cells, which suppress proliferation and interleukin-2 (IL-2) production in autoreactive $CD25–CD4^+$ and $CD8^+$ T cells [5]. Regulatory T cells are IL-2 dependent with constitutively expressed CD25 (IL-2 receptor) and IL-7 independent without CD127 (IL-7 receptor). Natural killer (NK) T cells and other T-cell subsets producing transforming growth factor-β (TGF-β) and IL-10 have also been associated with immune regulation.

The genetics of autoimmune disease

Autoimmune disease can be associated with either single gene defects or susceptibility genes as part of a complex multigenic trait. Four inherited disorders from single gene defects have been described, which have contributed further insights into autoimmune disease mechanisms in humans (Table 66.1) [6–9]. These include defects in (1) autoimmune regulator (AIRE)-dependent negative selection in the thymus, (2) cytotoxic T-lymphocyte antigen-4 (CTLA-4)-dependent inhibition of T-cell function,

Table 66.1 Single gene defects associated with autoimmunity

Autoimmune disease	Gene defect	Mechanisms of autoimmunity
APS1[a] [6]	*AIRE*	Defective expression of thymic self-antigens
Graves disease, Type I diabetes, others [7]	*CTLA4*	Defect in inhibitory signaling
ALPS[b] [8]	*FAS, FASL*	Defect in apoptosis
IPEX[c] [9]	*FOXP3*	Decreased regulatory T cells

[a] Autoimmune polyglandular syndrome type 1.
[b] Autoimmune lymphoproliferative syndrome.
[c] Immunodysregulation, polyendocrinopathy, enteropathy, X-linked syndrome.

(3) Fas/FasL (Fas ligand)-dependent apoptosis of B and T cells that recognize self-antigens, and (4) FoxP3-dependent development of regulatory T cells.

The most common autoimmune diseases are considered to result from alleles of susceptibility genes at multiple loci, environmental triggers, and stochastic events. The disease-associated alleles of susceptibility genes have been shown to confer only modest risk for the development of an autoimmune disease and were first identified among the MHC genes [10]. Most correlations of autoimmune diseases were with MHC class II rather than class I molecules. Other susceptibility genes affect, in general, pathways for activation/inhibition of T cells (IL-7R, IL-2R, PDCD-1, PTPN22, CTLA4) or presentation of self-antigens (insulin, PADI4) [11–13]. It is unclear to what extent environmental factors contribute to the risk of developing autoimmune disease. Environmental factors including hydralazine, contaminated rapeseed oil, L-tryptophan, and *Borrelia burgdorferi* infections in association with specific alleles of the MHC loci have been shown to increase the risk of an autoimmune disease.

Family or twin studies may provide further information about the contribution of genetic factors to the onset or presentation of autoimmune diseases. In general, the disease concordance rates among monozygotic twins was ≥3-fold greater than in dizygotic twins for rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), type I diabetes mellitus (DM), and multiple sclerosis (MS) [14,15]. The average concordance rates reported for monozygotic twins ranged from 15 to 30% for DM, MS, SLE, and RA. It has also been reported that there was a higher risk for many autoimmune diseases in other family relatives. Although genetic factors appear to play a role in the development of autoimmune diseases, the relatively low penetrance as noted in the monozygotic twins indicate that non-genetic factors are also important.

Preclinical models of autoimmunity and hematopoietic cell transplantation

There are two potential approaches utilizing HCT to consider for the treatment of autoimmune diseases. The first approach is autologous HCT after high-dose immunosuppressive therapy (HDIT). The therapeutic effects derive from the high-dose cytotoxic immunosuppression. Allogeneic HCT, as the second approach, can be performed after either high-dose or reduced-intensity conditioning regimens. The therapeutic effect of this approach likely derives from the eradication of autoreactive immune effector cells when complete donor hematopoietic chimerism is established. However, remissions of autoimmune diseases have been reported after establishing only mixed hematopoietic chimerism. Therefore, it is likely that the immunomodulation from establishing the donor graft including effects on regulatory mechanisms may have a self-tolerizing effect even if there are persistent host autoreactive immune cells.

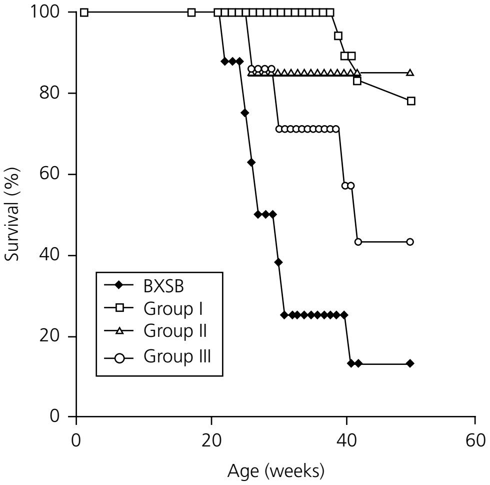

Figure 66.1 Survival curves of BXSB mice (spontaneous lupus-like syndrome) after treatment with 9.5 Gy of TBI (^{137}Cs irradiation; 0.70 Gy/min) and transplantation with T-cell-depleted marrow cells intravenously at 16 weeks of age from BXSB or normal BALB/c donors after the development of the autoimmune disease. The transplant groups were: BALB/c + BXSB → BXSB group (squares; group I; $n = 18$); BALB/c → BXSB group (triangles; group II, $n = 8$); and BXSB → BXSB group (circles; group III; $n = 7$). Untreated BXSB mice served as controls (diamonds; $n = 8$). Compared with untreated controls or group III (pseudoautologous), survival was improved in recipients of the allogeneic marrow grafts. Source: Wang et al. 1999 [16]. Reproduced with permission of the National Academy of Sciences, USA.

There are two types of models for autoimmune disease in which studies of autologous and allogeneic HCT have been conducted: (1) a spontaneously developed autoimmune disease, such as a lupus-like systemic condition in NZB (New Zealand black) mice, or an organ-specific condition, such as diabetes mellitus in NOD (non-obese diabetic) mice, and (2) antigen-induced autoimmune diseases, such as adjuvant arthritis and experimental allergic encephalomyelitis (EAE). In the spontaneous autoimmune disease models, high-dose cytotoxic therapy and syngeneic bone marrow transplantation early in life did not prevent the development of the clinical or pathologic autoimmune process, whereas allogeneic marrow transplants from an autoimmune-resistant strain prevented and, when given early after disease onset, ameliorated the autoimmune manifestations (Figure 66.1) [16,17].

In contrast to the experience in models of spontaneous-onset autoimmune diseases, studies of antigen-induced autoimmune diseases have shown therapeutic responses in recipients after high-dose cytotoxic immunosuppressive treatments and syngeneic or pseudoautologous HCT. Pseudoautologous donors were syngeneic donors with the same disease severity as the recipients at the time of HCT. Experimental allergic encephalomyelitis, an experimental model for MS, may be induced in Buffalo rats and SJL/J mice by active immunization with myelin basic protein (MBP). In this model, high-dose therapy with total body irradiation (TBI) or cyclophosphamide followed by allogeneic, syngeneic, or autologous marrow rescue can prevent or ameliorate disease activity [18,19]. Allogeneic HCT was superior in preventing spontaneous and induced relapses from reimmunization of MBP. In rats, after immunization with a unique peptide fragment of myelin, the CD4$^+$

T-lymphocyte cell initiating EAE is skewed towards overutilization of the V_β8.2 T-cell receptor. When analyzed by reverse transcriptase polymerase chain reaction and in situ hybridization, V_β8.2 T-lymphocytes were not detected in the central nervous system (CNS) after HDIT and syngeneic HCT [20]. Therefore, high-dose therapy was able to eliminate the effector lymphocytes responsible for EAE from the CNS in this model. Similarly, in adjuvant-induced arthritis, the prevention of relapses after HDIT followed by syngeneic HCT and repeat immunization is consistent with a tolerizing effect to the inciting antigens. Increased intensity of the high-dose cytotoxic immunosuppression resulted in more effective induction of remissions and less relapses [21].

Observations in preclinical models of spontaneous-onset autoimmune diseases support the use of allogeneic HCT for those human autoimmune diseases related to single gene disorders with high penetrance (e.g., IPEX syndrome). However, for the other more common human autoimmune diseases, in which environmental or stochastic factors may play a larger role for triggering disease onset, the preclinical data support the investigations of HDIT and autologous HCT.

Outcomes in patients with autoimmune diseases transplanted for another primary disease

Observations in patients with hematologic disorders and a concomitant autoimmune disease gave us our first understanding that the response of human autoimmune diseases to allogeneic HCT could be comparable to the experience in the preclinical models (Table 66.2) [22–36]. Baldwin et al. first reported sustained remissions in patients who were transplanted with severe aplastic anemia (SAA) but also had a diagnosis of RA [22]. Follow-up was short and there were early transplant-related deaths. Subsequent case reports of patients transplanted with a concomitant diagnosis of RA confirmed that remissions could be achieved and be sustained for >20 years [27]. It was also noted that three of the nine patients with RA relapsed after allogeneic HCT. One of the relapses was transient with a subsequent treatment-free remission of 11 years. In one of the two sustained relapses for which data were available, the recipient had complete donor hematopoietic chimerism, but the human leukocyte antigen (HLA)-identical donor was serologically positive for rheumatoid factor but without clinical disease [23].

Sustained remissions and some relapses were also observed in patients with other concomitant autoimmune diseases after allogeneic HCT. Four of five patients with Crohn disease had sustained remission with follow-up for 4.5–15.3 years after allogeneic HCT for leukemia [32]. The one patient who relapsed with Crohn disease had mixed hematopoietic chimerism detected at 3 months after HCT. There were insufficient data from the case reports to develop an understanding of why relapses occurred after allogeneic HCT. In all but one of the cases reporting the use of allogeneic HCT for concomitant autoimmune diseases, the donor was an HLA-identical sibling. Therefore, one possible explanation for recurrence of the autoimmune diseases may be the presence of shared genetic factors between the related donors and recipients. Another possible explanation is the persistence of host immune cells resulting in recurrence of disease activity. These case reports, although small in number, were important in establishing our understanding of the potential role of allogeneic HCT for treatment of patients with severe autoimmune diseases.

High-dose immunosuppressive therapy and autologous hematopoietic cell transplantation for autoimmune diseases: clinical experience

HDIT has been performed most commonly for MS, systemic sclerosis (SSc), SLE, RA, juvenile idiopathic arthritis (JIA), and immune cytopenias [37]. HDIT regimens that have been investigated have had varying intensities. High-dose single-agent cyclophosphamide has been considered a low-intensity regimen [38]. It is highly immunosuppressive but is not myeloablative. Clinical trials of high-dose cyclophosphamide have been conducted with and without the support of autologous HCT. Regimens that included TBI or high-dose busulfan were considered high intensity and required support with autologous HCT.

Patient selection

Patients eligible for clinical trials of HDIT were generally those with severe autoimmune disease (life threatening or threatening the function of critical internal organs) and had failed conventional therapy. Although the criteria for selecting patients depended upon the type of autoimmune disease, it was usually required that patients have a poor prognosis based on the activity and severity of the disease.

Collection and processing of the hematopoietic cell graft

Although some of the earliest adult cases were transplanted with marrow grafts, most of the later patients were transplanted with hematopoietic cell grafts harvested from the peripheral blood [39].

Table 66.2 Outcomes in patients with autoimmune diseases transplanted with an allogeneic hematopoietic cell graft for another primary disease

Autoimmune disease	Hematologic disease	Evaluable patients (total) (*n*)	Remission of autoimmune disease (after HCT) (*n*)	Outcome (alive at last follow-up) (*n*)	Follow-up
Rheumatoid arthritis [22–28]	SAA (*n* = 8), 1 MM	9	7 (2 relapses + 1 transient relapse)	6	2 mo–21 yr
Systemic lupus erythematosus [29]	SAA	1	1[a] (ANA titer +)	1	15 yr
Psoriatic arthritis [30,31]	AML, CML (*n* = 3)	4	3 (1 relapse)	3	1, 3, 5, 5 yr
Ulcerative colitis [30]	AML	1	1	1	4 yr
Crohn disease [32]	CML	5	4[b]	5	4.5–15.3 yr
Multiple sclerosis [33–36]	CML (*n* = 2), LGL leukemia, AML	4	3	3	1, 2, 3, 4 yr

AML, acute myeloid leukemia; ALL, acute lymphoblastic leukemia; ANA, antinuclear antibody; CML, chronic myelogenous leukemia; LGL, large granular lymphocytes; MM, multiple myeloma; SAA, severe aplastic anemia.

[a] Clinical remission but ANA remained positive.

[b] Relapse occurred in one patient with mixed chimerism.

Marrow was the preferred source of hematopoietic stem cells for many pediatric patients [40]. The optimal dose of peripheral blood CD34$^+$ cells for successful engraftment was $2–5 \times 10^6$/kg in patients with hematologic malignancies, and therefore this was the number targeted for collection in patients with autoimmune diseases. In a multicenter, retrospective analysis, eight of 173 patients (4.6%) failed to mobilize sufficient numbers of CD34$^+$ cells to allow them to proceed to HDIT [39]. Five of these eight patients eventually had adequate numbers of cells harvested by either a supplemental marrow harvest ($n = 2$) or a successful second mobilization ($n = 3$).

Early in the clinical trial experience of HDIT for autoimmune diseases, it was observed that some patients had disease flares during mobilization. In one review, five of 56 patients mobilized with granulocyte colony-stimulating factor (G-CSF) alone had exacerbations of the autoimmune disease (MS, $n = 2$; RA, $n = 3$) [39]. There have been other reports of exacerbations during mobilization of MS and RA patients with G-CSF alone [41,42]. Most exacerbations were transient, but one patient with MS died from the development of severe brainstem dysfunction. As a result of these early flares, most patients have now been mobilized with a combination of cyclophosphamide and G-CSF. In 117 patients mobilized with this combination, no exacerbations were observed. In fact, after mobilization with cyclophosphamide, an improvement was noted in the underlying autoimmune disease. The addition of cyclophosphamide to G-CSF also improved the yield of progenitor cells after mobilization [39]. However, there were three patient deaths in this report from either cyclophosphamide-related toxicity or infections. In another report of 126 patients from a single center who were mobilized with a combination of G-CSF and cyclophosphamide, there was one patient death from infection [43]. Four mild exacerbations of disease and seven infectious events were also observed during mobilization with a cyclophosphamide-based regimen. Another mobilization strategy that has been used in 22 MS patients without disease exacerbations or infections is the combination of prednisone and G-CSF [44]. G-CSF alone has been used to mobilize 34 patients with SSc without any significant disease exacerbations except for a few cases in which there was an increase in telangiectasias or skin tightness [45]. The risk of exacerbations during mobilization using G-CSF alone may be related to the type of autoimmune disease. The use of cyclophosphamide as part of the mobilization regimen should be carefully considered, possibly by the type of autoimmune disease because of the potential risks.

Many of the reported clinical trials used T-cell-depleted autologous grafts as a strategy to prevent recurrence of the autoimmune disease. This strategy was based on observations in preclinical models in which the autoimmune disease could be adoptively transferred with T cells. In most of the clinical trials, CD34 selection was performed and resulted in a 3–4 log depletion of T cells in the autologous graft. Further T- and B-cell depletion was carried out in some clinical trials after the CD34 selection. The importance of T-cell depletion for prevention of progression or relapse was addressed in a retrospective analysis of registry data from the European Group for Blood and Marrow Transplantation (EBMT). There was no significant effect associated with T-cell depletion of the graft [38]. In the most recent analysis of the EBMT registry data, T-cell depletion did not effect 100-day treatment related mortality, 3-year progression-free survival, or 3-year overall survival [37]. Although the risk of infection may be increased with T-cell depletion of the autologous graft, the incidence of infectious disease was low if these patients are managed with the same infection prophylaxis strategies as used for patients after allogeneic HCT [40,46]. The contribution of T-cell depletion of the autologous hematopoietic cell graft to the prevention of progression or relapse remains to be determined in future clinical trials.

High-dose immunosuppressive therapy regimens

The early rationale for HDIT was the systematic depletion of autoreactive immune effector cells. With long-term follow-up of the pilot studies of HDIT with autologous HCT now available, it has been observed that there is a high initial response rate and a significant proportion of patients have achieved sustained remissions [40,45,47–49]. The clinical response early after HDIT likely resulted from the overall reduction of immune effector cells responsible for the autoimmune disease. The sustained response observed after recovery of the lymphocyte counts at 2 years may have resulted from a sustained immunomodulatory effect of the HDIT regimen [46,50,51]. Randomized clinical trials need to be completed to confirm that the clinical responses after HDIT are an improvement over what might have been expected from conventional management strategies.

The intensity of the HDIT regimen appears to be important for the prevention of disease progression. In a report of 473 patients from the EBMT registry, sustained responses were observed in 78% of patients after a regimen with high-intensity conditioning compared with 68% with intermediate- and 30% with low-intensity conditioning regimens ($p = 0.0001$) [38]. Regimens that included busulfan or TBI in combination with cyclophosphamide were placed in the high-intensity conditioning group, and cyclophosphamide alone was placed in the low-intensity conditioning group. All other regimens were considered of intermediate intensity. The analysis of the registry data had some limitations, including variability of the diagnoses, patient selection criteria, and treatments (in addition to having imbalances between diagnosis and type of HDIT regimen), but a dose intensity–response effect on treatment outcomes was evident.

One of the most frequently used HDIT regimens was high-dose single-agent cyclophosphamide (200 mg/kg) followed by autologous HCT for hematopoietic support [38]. A small study compared 100 with 200 mg/kg of cyclophosphamide followed by HCT in patients with RA. Remissions were longer with the higher dose of cyclophosphamide, but all patients relapsed [52]. The high relapse rates after HDIT may be a unique feature of RA in comparison with other autoimmune diseases. The addition of antithymocyte globulin (ATG) to cyclophosphamide may improve the response rate and duration. Since it is not myeloablative, high-dose cyclophosphamide (200 mg/kg) as a single agent without autologous HCT has been reported for the treatment of autoimmune diseases or immune-mediated diseases such as aplastic anemia [53,54]. The median time to recovery of neutrophils counts was 2–3 days longer without the support of an autologous hematopoietic cell graft but the upper limit of the range was 7 days longer. The relapse rate was also high in SLE patients ($n = 14$) after high-dose cyclophosphamide without HCT, but a significant proportion (36%) had durable complete remissions. In this small experience, relapse rate was high even if the infusion of an autologous hematopoietic cell graft was withheld.

High-dose combination chemotherapy with BCNU, etoposide, cytosine arabinoside (Ara-C), and melphalan (BEAM) with or without ATG was considered an intermediate-intensity regimen [38]. For autoimmune diseases, this regimen has most commonly been used for the treatment of MS [55]. It has been well tolerated in this group of patients and no significant data exist for other autoimmune diseases. Regimens with either TBI or busulfan in combination with cyclophosphamide were considered to be high intensity [40,44,45,56–58]. A pilot study of busulfan in combination with cyclophosphamide has been reported for the treatment of MS [58]. The use of TBI in combination with cyclophosphamide has been reported in clinical trials of HDIT for MS, SSc, and JIA. TBI is highly immunosuppressive and was shown to be effective in preclinical models of autoimmune disease [21,59]. Organs can be shielded with lead during TBI to protect them from the potential adverse effects of this form of cytotoxic therapy, which is not possible with systemic chemotherapy. TBI has the potential for killing cycling and non-cycling stem cells and also immune effector cells. Support with an infusion of autologous hematopoietic stem cells is required after both intermediate- and high-intensity HDIT regimens to prevent prolonged pancytopenia or lack of hematopoietic recovery.

From the EBMT registry, treatment-related mortality at day 100 was 5% and 4% in the groups who received the high and the low conditioning intensity regimens, respectively [37]. There was no difference in 100-day treatment-related mortality based on the intensity of the HDIT regimen but there was an association with the type of autoimmune disease and the transplant's center experience. Treatment-related mortality resulted primarily from infections and severe organ toxicity. Several fatal cases and one non-fatal case of Epstein–Barr virus (EBV)-associated post-transplant lymphoproliferative disorder (PTLD) have been reported [57,60]. In patients who have had a high-intensity immunosuppressive regimen, early detection of EBV reactivation and treatment with rituximab may prevent the clinical manifestations of PTLD. The risks of infectious complications and organ toxicities after HDIT are closely related to the type of autoimmune disease being treated. Patients with MS and RA had a lower treatment-related mortality than patients with SSc and SLE who had significant internal organ involvement at the time of transplant. Prolonged or intensive pre-transplant treatment with immunosuppressive agents including corticosteroids, as in the management of patients with severe SLE, likely predispose to infectious complications after HDIT. Better patient selection and modifications to the treatment regimen appear to have reduced the risks of treatment-related mortality in recent years [37]. Long-term complications after high-dose cytotoxic therapy include the risk for secondary myelodysplastic syndrome (MDS) and leukemia [37,45,57]. In one of the reported cases of MDS, evidence of clonal abnormalities was found in cryopreserved pre-transplant hematopoietic cells. The intensity and duration of the pre-transplant chemotherapy are known to be an additional risk factor for the development of secondary MDS and leukemia. Secondary autoimmune diseases (other than the one for which patients were transplanted) have been described late after HDIT and autologous HCT [45,61,62]. Alemtuzumab in the HDIT regimen may increase the risk of this occurring [61,63].

Immune reconstitution after a high-dose immunosuppressive therapy regimen

NK-cell counts recovered by 1 month and this was followed by recovery of B- and $CD8^+$ T-cell counts by 6–12 months after HDIT. There was a slower recovery of $CD4^+$ T-cell counts, which were low-normal by 2 years [46]. Immune recovery at 2 years after HDIT was associated with increasing thymic-derived naïve $CD4^+$ T cells (Figure 66.2). There was an increase in T-cell receptor excision circles (TRECs) (a marker for recent thymic emigrants) in $CD4^+$ T cells at 1 and 2 years after HDIT. There was a steady decrease over time in $CD4^+$ central memory T cells. $CD4^+$ effector memory cells were relatively increased at 6 months after HDIT, likely from homeostatic proliferation, but had recovered to normal levels by 2 years. There were no significant changes in the $CD8^+$ T-cell subsets. There was an increase in $CD4^+$ and $CD8^+$ regulatory T cells, and broader clonal diversity than was present before HDIT [50,51,64,65]. In association with the increased levels of naïve $CD4^+$ T cells, there was hypertrophy of the thymus at 1 and 2 years compared with baseline, especially in the younger patients (less than 43 years of age). This evidence suggested a thymic origin for the recovery of the $CD4^+$ T-cell repertoire after HDIT and autologous HCT. Even though B-cell counts were very low in the first 3 months after HDIT, median serum levels of immunoglobulin G specific for tetanus toxoid, *Haemophilus influenzae* and *Streptococcus pneumoniae*, were normal. The clinical responses to HDIT that have persisted for 5 years or longer may have resulted from these immunomodulatory effects associated with HDIT.

Specific autoimmune diseases and hematopoietic cell transplantation

Clinical trials of HDIT and autologous HCT have been conducted for specific autoimmune diseases, and in some cases the results from long-term follow-up evaluations are available.

Multiple sclerosis

MS is an autoimmune inflammatory disorder of the CNS manifesting as acute focal demyelination and axonal loss with limited remyelination and focal sclerotic changes [66]. Recurrent inflammatory events result in the development of chronic multiple sclerotic plaques in the brain and spinal cord. MS has a lifetime risk of 1 in 400, affects 350,000 people in the United States, and is potentially the most common cause of neurological disability in young adults. Seven of 27 monozygotic pairs (25.9%) and one of 43 dizygotic pairs (2.3%) were concordant for MS, which suggests that there is a genetic predisposition for development of MS with a contribution of environmental factors [15]. Using genome-wide association studies, HLA DRB*1501 has been identified as an MHC risk locus. Other susceptibility loci were identified in the IL-2 receptor and IL-7 receptor which are expressed on regulatory T cells [66]. It is postulated that myelin proteins, such as MBP, proteolipid protein (PLP), and perhaps myelin oligodendrocyte glycoprotein (MOG), are targeted by pathogenic $CD4^+$ T cells in patients with MS. The pathology shows a predominant T-cell response both in perivascular spaces and in the demyelinated lesion. Axonal injury is evident not only in the acute inflammatory and the chronic non-enhancing lesions but also in the normal-appearing white matter.

The clinical manifestations of the disease may include loss of vision from optic neuritis, diplopia, sensory loss and paresthesias, vertigo, fecal and/or urinary incontinence, impotence, intellectual decline, paroxysmal pain, recurrent infections, loss of coordination, or paralysis. Clinical diagnosis depends on two or more attacks involving non-contiguous anatomic regions separated by at least 1 month or progression of symptoms or signs for more than 6 months. About 85% of patients present with relapsing–remitting MS (RRMS), and over 10 years about 50% of these patients will develop secondary progressive disease with cumulative disability. The other 15% of patients have progressive disease from onset (primary). The standard for measuring outcome in studies of MS is the Kurtzke Expanded Disability Status Scale (EDSS) and, more recently, the Multiple Sclerosis Functional Composite (MSFC).

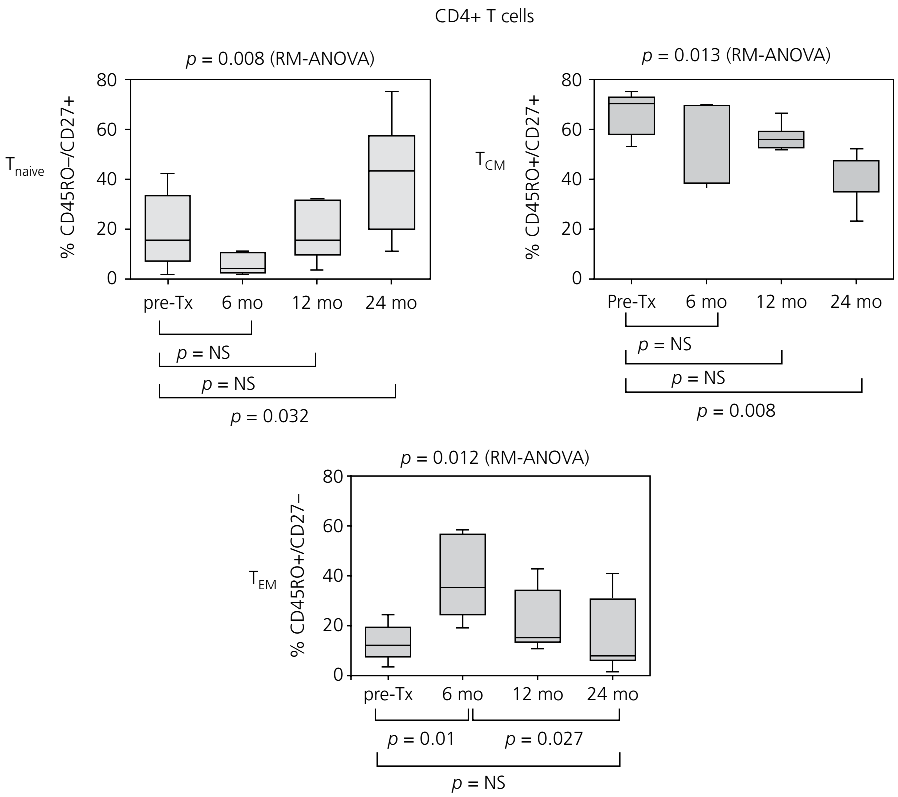

Figure 66.2 Naïve CD4$^+$ T cells increased and central memory CD4$^+$ T cells decreased at 2 years after HDIT and autologous HCT for MS. In a longitudinal analysis of T-cell subsets after HDIT and autologous HCT, a trend towards reduction of naive (CD45RA$^+$/CD45RO$^-$/CD27$^+$) CD4$^+$ T cells was observed at 6 months, consistent with an increase in effector memory (EM) phenotypes resulting from homeostatic proliferation in a lymphopenic environment. Central memory (CM; CD45RA$^-$/CD45RO$^+$/CD27$^+$) CD4$^+$ cells decreased steadily during the follow-up. The proportion of EM (CD45RA$^-$/CD45RO$^+$/CD27$^-$) CD4$^+$ T cells rose significantly at 6 months after HSCT and later declined toward baseline levels after the gradual recovery of the absolute CD4$^+$ T-cell numbers. At the 2-year follow-up, the frequency of naïve CD4$^+$ T cells had increased by 118% as compared with pre-therapy ($p = 0.032$). Correspondingly, CM CD4$^+$ T cells had decreased by 38% at 2 years after therapy ($p = 0.008$). The frequencies of the EM CD4$^+$ T cells did not change significantly at the 2-year follow-up compared with the baseline. These data support the concept that there is significant immunomodulation at 2 years after HDIT and autologous HCT, and this may explain the observed durable clinical remissions in a significant proportion of patients with autoimmune disease. Source: Muraro et al. 2005 [50]. Reproduced with permission of Rockefeller University Press.

There is little influence of MS on survival until at least 15 years after onset. At 20 years after onset, patients with MS had 85% of the expected survival. Prognostic factors for worse outcome have been identified and include increased age, short intervals between relapses, high frequency of relapses after disease onset, and early significant disability. Despite responses to immunomodulating agents, no standard therapy is curative or has been demonstrated to prevent the development of a progressive clinical course. Agents that have been demonstrated to be effective as disease-modifying therapies in RRMS include interferon (IFN) beta-1a, IFN beta-1b, glatiramer acetate (GA), mitoxantrone, natalizumab, fingolimod, teriflunomide, and dimethyl fumarate. Treatment reduced the clinical relapse rates in patients with RRMS by 30–68%, with the newer agents being more effective than IFN or GA. These agents, however, remain inadequate to prevent relapses and progression completely. No effective therapy has yet been identified for primary or secondary progressive MS.

The results of phase II clinical trials of HDIT and autologous HCT for MS have been reported from many North American and European centers (Table 66.3) [44,55–58,67–69]. Although there was variability in the design of each of these clinical trials, they all included patients with advanced MS and the progressive type of the disease. All patients received high-dose combination chemotherapy or TBI and cyclophosphamide. In seven of the eight clinical trials, the hematopoietic cell grafts were mobilized from the peripheral blood, and all but one of the trials included T-cell depletion with CD34 selection. Overall treatment-related mortality in these clinical trials was 2.8% (4/145) and the progression-free survival or rate of neurologic stability reported in the individual clinical trials ranged from 36 to 95% at 2–3 years after treatment. Five patients (3.5%) died after progression of disease and further loss of neurologic function or other complications.

Although no direct comparisons can be made between the clinical trials regarding outcomes, there did not appear to be any advantage to including TBI in the HDIT regimen. In a report by Saccardi et al., progression-free survival at 6 years was 95% [55] (Figure 66.3). In a long-term follow-up report of one of the earliest studies, progression-free survival was 44% at 15 years in patients with active CNS disease at baseline and 10% in patients without active disease at baseline [48]. Although magnetic resonance imaging (MRI) after transplant showed a marked reduction in Gd-enhancing brain lesions in all the groups studied compared with baseline, it is still uncertain if the continued loss of neurologic function observed in patients with progressive MS is the result of a degenerative process or a failure to control completely inflammation related to the autoimmune disease. Randomized clinical trials

Table 66.3 Clinical trials of HDIT and autologous HCT for multiple sclerosis

Study	No. of patients (*n*)	MS type (*n*)	Median EDSS[a] (range)	Mobilization	High-dose therapy	T-cell depletion	Median follow-up (range) (months)	Treatment-/ disease-relatedmortality(*n*)	Clinical result

ATG, antithymocyte globulin; B, BCNU; BEAM, BCNU, etoposide, cytosine arabinoside (Ara-C), melphalan; BU, busulfan; CY, cyclophosphamide; PFS, progression-free survival; PP, primary progressive; PR, progressive relapsing; RR, relapse-remitting; SP, secondary progressive; TBI, total body irradiation. EDSS, Expanded Disability Status Scale.

[a] In brief, the functional levels of the Expanded Disability Status Scale (EDSS) are graded from 0 to 10 points and include changes in increments of 0.5 points. An EDSS score of 0 indicates a normal neurologic examination in all functional systems (FS). An EDSS score of 10 indicates death from MS. Most of the MS patients who entered these clinical trials of HDIT and autologous HCT had an EDSS score of 5.0–8.0. In general, the function of patients at these different EDSS scores are as follows:

5.0 Ambulant 200 m without aids, difficulty to work full day, FS grade 5.
6.0 Intermittent or unilateral walking aid for 100 m.
7.0 Wheelchair-bound (walking <5 m with assistance). Able to transfer and use wheelchair alone. Sometimes severe pyramidal grade 5.
8.0 Bed- and chair-bound, self-care functions retained (arm function retained), sitting out of bed most of the day.

[b] One patient with progression of MS was started on interferon beta after a relapse, developed a factor VIII inhibitor at 14 months, and died at 28 months after HDIT and autologous HCT.

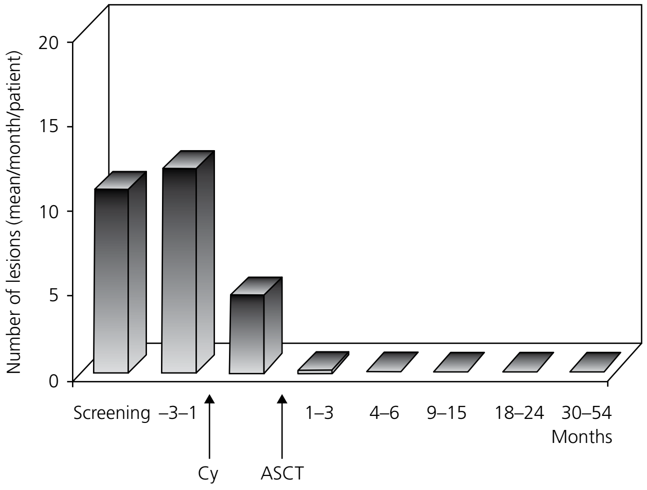

Figure 66.3 Gadolinium-enhancing lesions in the brain after HDIT (BEAM) and autologous HCT: MRI results. The mean numbers of gadolinium-enhancing lesions in the brain per month per patient are reported at baseline during the 3-month period before mobilization (-3–1), after mobilization (Cy), and after transplantation (ASCT) to last follow-up. The duration of gadolinium-enhancement of a new lesion is approximately 4 weeks so the presence of gadolinium-enhancing lesions in the central nervous system indicates recently active disease. After HDIT and autologous HCT there is a marked reduction in enhancing lesions for the duration of the follow-up. Source: Saccardi et al. 2005 [55]. Reproduced with permission of the American Society of Hematology.

need to be completed to confirm if there is a therapeutic benefit of HDIT and autologous HCT in this patient population with advanced MS. More recent studies of HDIT and autologous HCT have focused on patients with RRMS and less advanced neurologic disabilities at baseline [63]. After a mean follow-up of 37 months in a study by Burt et al. [63], progression-free survival was 100% and 16 of 21 patients were free from relapse. Significant improvements were noted in neurological disability and quality of life measurements (Figure 66.4).

Systemic sclerosis

SSc is an uncommon disabling autoimmune disease that is associated with a high mortality. In studies performed in different geographic settings, the prevalence has ranged from 28 to 286 per million, and the incidence has been reported to range from 3.7 to 19.2 per million [70]. SSc is characterized by two major clinical features: (1) a non-inflammatory small-vessel vasculopathy and (2) fibrosis of the skin and multiple internal organs [70]. There is evidence of immune dysregulation with SSc-specific autoantibodies, mononuclear cell infiltrates in several affected organs, and elevated cytokine levels in tissue and serum. The anticentromere antibody is found in the group with limited cutaneous SSc, and the anti-topoisomerase I antibody (Scl-70) is found in 30–40% of subjects with diffuse cutaneous SSc. Antinuclear antibodies occur in 95% of subjects overall. Diffuse cutaneous SSc is a more severe manifestation of disease than limited cutaneous SSc. It has a higher mortality and is associated with substantial morbidity as a consequence of digital ischemia/skin ulcerations from the vasculopathy, both truncal and acral scleroderma, interstitial lung

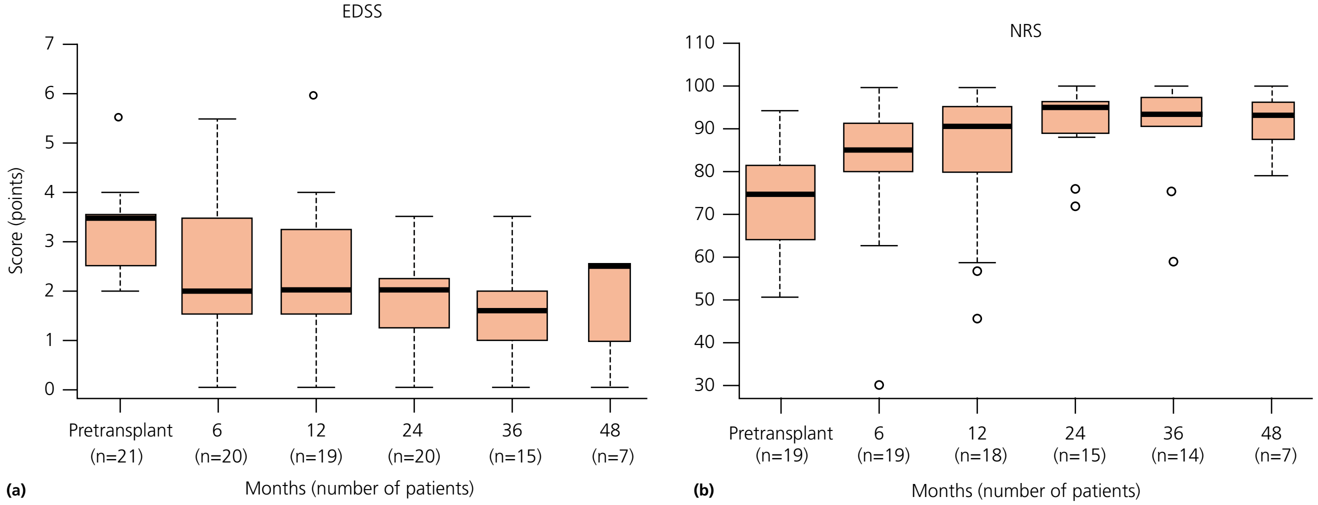

Figure 66.4 Clinical improvement after high-dose immunosuppressive therapy and autologous HCT as measured by the Kurtzke Extended Disability Status Scale (EDSS) and the Scripps Neurological Rating Scale (NRS). (a) The EDSS is a neurologic performance scale that increases with increasing disability at intervals of 0.5 points from 0 (healthy) to 10 (death from neurologic disability). (b) The NRS is a neurological performance scale that increases at intervals of 1 point, with decreasing disability going from 0 points (dead) to 100 points (healthy). Although all patients had EDSS score recorded before transplantation, a few missed one or more of the pre-transplantation tests and a few patients declined a post-transplantation interval follow-up, but did return for the next follow-up visit. Thick lines are medians; boxes are values for upper and lower quartiles. Open circles are outliers, defined as values that are more than 1.5 times the 25th or 75th percentiles. Source: Burt et al. 2009 [63]. Reproduced with permission of Elsevier.

disease, hypertensive renal crisis, diffuse gastrointestinal disease, and myocardial involvement. In one study of the natural history of SSc, survival was <80% at 2 years, <50% at 8.5 years, and <30% at 12 years [71]. Other studies have confirmed the poor survival and poor risk features of SSc, especially when there is internal organ involvement, and that standardized mortality ratios had not changed significantly over the previous 40 years [72–74]. Scoring the skin for the extent of scleroderma improves the prediction of prognosis [75]. The modified Health Assessment Questionnaire Disability Index (mHAQ) is a validated tool for measuring the effect of disease on overall function [76].

Immunosuppressive therapies investigated for severe SSc have been inadequate or ineffective. Cyclophosphamide may be considered a standard of care for individuals with early and severe SSc, particularly those with pulmonary involvement, but the therapeutic benefits are very modest [77]. There are no controlled, prospective clinical trials that demonstrate efficacy of any other conventionally dosed immunomodulatory agents. Important supportive care measures for patients with SSc include angiotensin-converting enzyme inhibitors for management of renal crisis and bosentan or other agents for management of pulmonary hypertension.

Patients selected for clinical trials of HDIT and autologous HCT for SSc had in general a poor prognosis based on the presence of diffuse cutaneous disease and internal organ involvement. In a study of patients (*n* = 26) who had already survived at least 6 months after high-dose cyclophosphamide only and HCT, survival was 96% and event-free survival was 64% at 5 years (Table 66.4) [78]. About half of the patients included in this study had diffuse cutaneous disease but without internal organ involvement.

In a multicenter study of a more intensive HDIT regimen consisting of TBI and cyclophosphamide in 34 patients with diffuse cutaneous disease and internal organ involvement, 17 of 27 (63%) evaluable patients who survived at least 1 year after HDIT had sustained responses (without progression or disease activation) at a median follow-up of 4 years [45]. Patients with sustained responses required no immune-based treatment after HDIT. There was a major improvement in the degree of scleroderma as measured by modified Rodman skin score (mRSS) and in overall function as measured by the mHAQ at final evaluation (Figure 66.5). Skin biopsies confirmed that the improvement in skin score was associated with a decrease in dermal fibrosis. Lung, heart, and kidney function, in general, remained clinically stable. The treatment-related mortality was 23% and the estimated progression-free survival was 64% at 5 years. Better patient selection and modifications to the treatment regimen have reduced treatment-related mortality. In a report from the EBMT on 57 patients in their registry with a median follow-up of 20 months, the cumulative probability of disease progression at 5 years was 48% and the cumulative probability of survival at 5 years was 72% [79].

In a more recent report on 90 patients, relapse-free and overall survival were 70 and 78% at 5 years, respectively [80]. Cardiovascular complications resulted in four of the five treatment-related deaths in this study and treatment-related mortality was 6%. In a randomized clinical trial with short follow-up (*n* = 19), HDIT was associated with improved progression-free survival at 12 months compared with pulse cyclophosphamide (Figure 66.6) [81]. Those patients who failed treatment with pulse cyclophosphamide had similar rates of improvement when crossed over to HDIT. Two randomized clinical trials of HDIT compared with pulse cyclophosphamide (ASTIS and SCOT) have completed enrollment and reports on the results are awaited.

Systemic lupus erythematosus

SLE is an autoimmune disorder that is characterized by the presence of antinuclear antibodies and immune complexes [82]. The incidence and prevalence have been estimated at 5.1 and 52.2 per 100,000, respectively. Numerous organ systems can be involved with SLE, and disease severity may vary from mild to life threatening. Antinuclear antibodies, anti-double-stranded DNA antibodies, and anti-Smith antibodies are present in 98, 70, and 25% of SLE

Table 66.4 Clinical trials of HDIT and autologous HCT for systemic sclerosis

Study	No. of patients (*n*)	Median BL DLCO % (range)	Median BL mRSS (range)	Mobilization	High-dose therapy	T-cell depletion	Median follow-up (range) (months)	Treatment-/ disease-related mortality	Clinical results
Nash [45]	34	61 (40–83)	30 (3–48)	G-CSF	TBI/CY + ATG	CD34 selection	48 (12–96)	8/4	PFS 64% Sustained response (evaluable, *n* = 27) 63% Improvement in skin score (*p* = 0.001) + stable lung function overall
Vonk [78]	28	55 (21–100)	32 (9–51)	G-CSF + CY	CY	CD34 selection	63 (12–90)	2/2[a]	EFS (evaluable, *n* = 26) 64% at 5 years and 57% at 7 years
Burt [81]	19	58 (29–82)	28 (6–48)	G-CSF + CY	CY + ATG	None	12 (all patients)	0/0	PFS 80%

BL, baseline; CY, cyclophosphamide (mobilization: 2 or 4 g/m^2; treatment: 120 mg/kg in combination with TBI or 200 mg/kg if single cytotoxic agent); DLCO, diffusion capacity of the lung for carbon monoxide; EFS, event-free survival; mRSS, modified Rodnan skin score (ranges from 0 to 51; increasing score indicates worsening scleroderma); PFS, progression-free survival.

[a] There was one additional death from lung cancer at 5 years after HDIT.

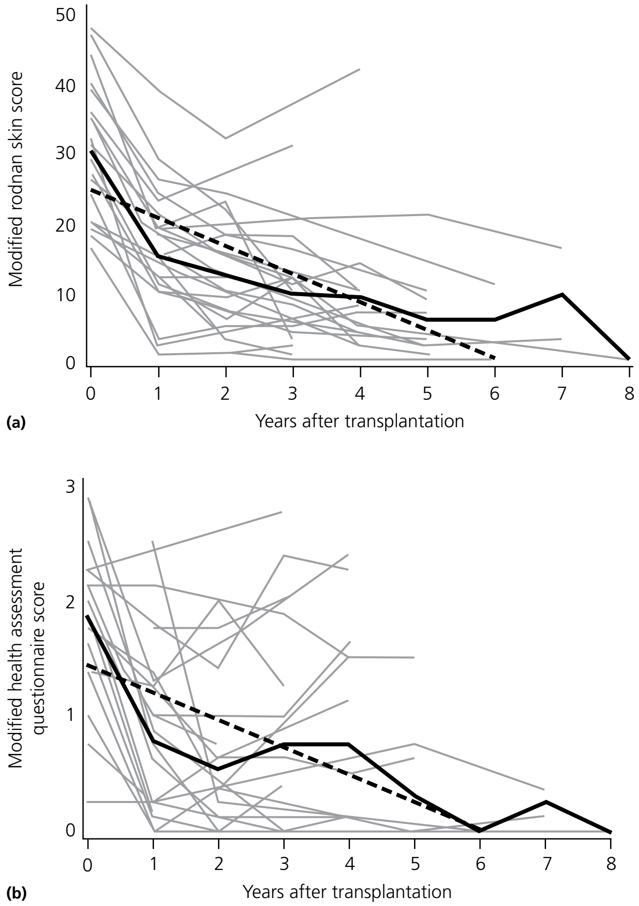

Figure 66.5 Changes in (a) the modified Rodnan skin score (mRSS) and (b) the modified Health Assessment Questionnaire (mHAQ) score after high-dose immunosuppressive therapy (HDIT) and autologous hematopoietic cell transplantation. A determination was made as to whether a parameter value was statistically significantly increasing or decreasing over time using a generalized estimating equation (GEE) model. The bold black dotted line represents an estimate of the modeled linear relationship between the parameter value and time and summarizes the results of the GEE models. The bold black solid line represents the mean value over time for the parameter of interest. The gray solid lines are parameter values for individual patients. The mean mRSS and mHAQ values decreased statistically significantly with time after HDIT as objective markers of less scleroderma and improved function (both $p < 0.001$). Source: Nash et al. 2007 [45]. Reproduced with permission of the American Society of Hematology.

patients, respectively. Overall, the 10-year survival of patients with SLE has been reported as 75–85%, with more than 90% surviving at 5 years [83]. In the group of SLE patients with severe disease who are refractory to standard treatment, survival is expected to be much lower. Standard treatment options are not curative and complete sustained remissions are rare. Antimalarials such as hydroxychloroquine reduce the frequency of disease flares. Low-dose corticosteroids are used for patients in whom disease symptoms have not been controlled by more conservative measures and disease flares are treated with high-dose corticosteroids. Belimumab is a human monoclonal antibody that targets and inhibits B-lymphocyte stimulator (BLyS) resulting in autoreactive B-cell apoptosis and is now approved by the US Food and Drug Administration (FDA) for the treatment of SLE. Agents such as cyclophosphamide, azathioprine, methotrexate, and mycophenolate mofetil have also been found effective for controlling disease activity [84]. The SLE Disease Activity Index (SLEDAI) is a validated tool for following disease activity over time [85].

Clinical trials of HDIT with and without HCT were conducted on patients with SLE who were refractory to standard therapies. In a single-center study (*n* = 50) of HDIT and HCT, patients were mobilized with G-CSF and cyclophosphamide, and the autologous graft was T-cell depleted by CD34 selection [47]. The HDIT regimen included high-dose cyclophosphamide (200 mg/kg) and ATG. The probabilities of overall and disease-free survival at 5 years were 84 and 50%, respectively. There was a significant improvement in the SLEDAI score and renal function stabilized (Figure 66.7). Titers for antinuclear and anti-double-stranded antibodies and complement levels improved after HDIT. Treatment-related mortality was 4% (*n* = 2) and both deaths occurred before HDIT. In comparison, a study of HDIT without HCT in patients with SLE, outcomes after single-agent, high-dose cyclophosphamide (200 mg/kg) (*n* = 14) were similar at a median follow-up of 27 months, with five patients (36%) reported as having durable complete remissions [53]. This approach avoids the reinfusion of cells that has the potential for causing a relapse. However, as might be expected, time to recovery of blood counts is longer, and this may contribute to increased morbidity from the procedure. There was no treatment-related mortality.

The EBMT registry reported the experience with HDIT and autologous HCT for SLE and significant disease responses were observed in 31/50 patients [86]. However, 10 of these 31 patients relapsed and some of the other patients remained on immunomodulatory therapy after HDIT to prevent relapse.

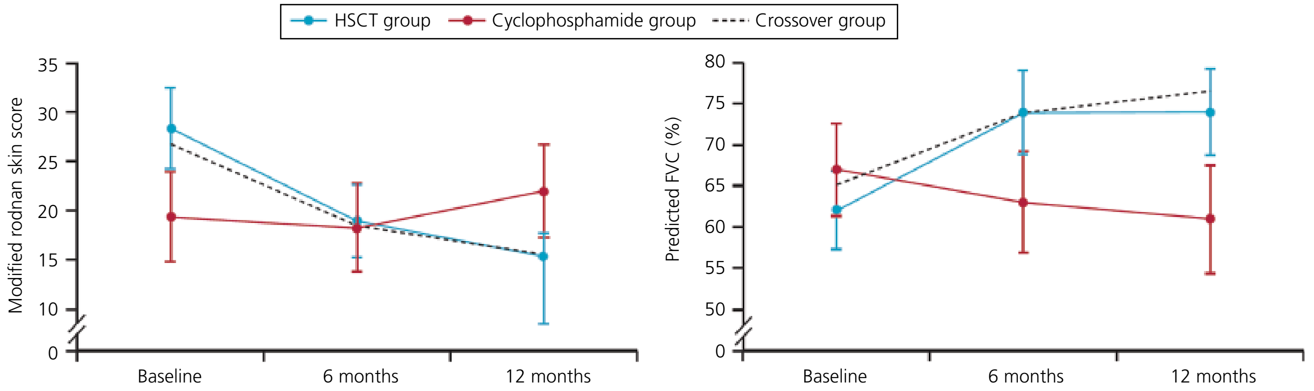

Figure 66.6 Improvement in skin score and lung function after HDIT and autologous HCT in comparison with conventional immunosuppressive therapy. All 10 patients randomly allocated to receive HSCT improved at or before 12 months' follow-up, compared with none of nine allocated to cyclophosphamide (odds ratio 110, 95% CI 14.04–∞; $p = 0.00001$). Eight of nine controls had disease progression (without interval improvement) compared with no patients treated by HSCT ($p = 0.001$), and seven patients switched to HSCT. Compared with baseline, data for 11 patients with follow-up to 2 years after HSCT suggested that improvements in mRSS ($p < 0.001$) and forced vital capacity ($p < 0.3$) persisted. Source: Burt et al. 2011 [81]. Reproduced with permission of Elsevier. (For a color version of this figure, please see the color plate section.)

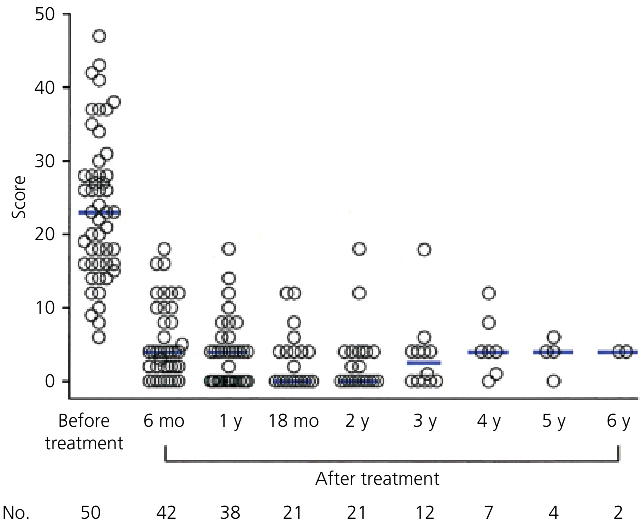

Figure 66.7 SLE disease activity index (SLEDAI) improves after HDIT and autologous HCT. In patients with severe refractory SLE there was a rapid decrease in the SLEDAI (indicating a decrease in disease activity), which was sustained in a substantial proportion of patients for more than 2 years after treatment. Source: Burt et al. 2006 [47]. Reproduced with permission of the American Medical Association.

Treatment-related mortality was 16%. Although the experience is limited, HDIT can induce a high percentage of disease responses in patients with SLE who had otherwise been refractory to standard therapy, and remissions have been durable in a significant proportion of patients.

Rheumatoid arthritis

RA is a chronic multisystem disease characterized by synovial inflammation, cartilage damage, and bone erosions [87]. The criteria for determining response to treatment have been defined by the American College of Rheumatology [88]. The disease affects about 0.8–1% of the population, and the incidence is 25 and 54 per 100,000 persons in men and women, respectively. The pathologic hallmark of RA is synovial inflammation with proliferation of macrophages and fibroblasts. If severe, the inflamed synovium develops into an invasive pannus that destroys cartilage and bone. The disease course can be mild with minimal damage of only a few joints, or severe with many inflamed, damaged joints. Other complications associated with RA are a vasculitis, cervical spine disease, lung nodules or interstitial fibrosis, and cardiac complications, including pericarditis. Risk of progression can be predicted by prognostic factors such as increased number of affected joints, high level of C-reactive protein, presence of rheumatoid factor, and extra-articular features of the disease. The risk of mortality is increased with more severe disease activity or one or more extra-articular disease manifestations [89–91]. There is a mortality of approximately 30% at 5 years for patients with the highest disease activity. There are many anticytokine or immunomodulatory agents approved for RA, including methotrexate, hydroxychloroquine, sulfasalazine, leflunamide, infliximab, adalimumab, etanercept, tocilizumab, abatacept, rituximab, and anakinra [87]. The goal of standard therapy is to relieve the signs and symptoms of the disease since none of these treatments is curative.

Four small clinical trials have been reported of HDIT for patients with RA who had failed standard treatment [52,92–95]. All patients received high-dose cyclophosphamide with or without ATG. The initial reports described early major responses in the majority of the patients. On long-term follow-up, it was noted that all 32 patients accrued to these clinical trials relapsed and required further treatment. However, many of these relapsed patients who had been refractory became responsive to treatment after HDIT. One study showed that after HDIT, there was a decrease in progression of joint damage compared with baseline [96]. No mortality was observed in any of the clinical trials. Seventy-six patients with RA who underwent HDIT and autologous HCT were available for analysis in the EBMT registry, and the outcomes were comparable to the experience reported from the clinical trials [97]. Cyclophosphamide alone was used as the HDIT regimen in 82% and the combination of cyclophosphamide and ATG in 9% of the patients. Major responses were observed in 67% of patients, and there was a significant reduction in the measures of disability. Most patients had restarted immunomodulatory treatment by 6 months after HDIT for persistent or recurrent disease activity. No treatment-related mortality was observed. It is unclear why there is a difference in response of

RA to HDIT compared with other autoimmune diseases. More durable responses might be obtained with more intense HDIT regimens, but this may further increase the risk for treatment-related mortality. Another strategy to decrease relapses or progression may be to add immunomodulatory therapy after HDIT.

Juvenile idiopathic arthritis

JIA is a heterogeneous group of chronic inflammatory diseases involving the joints and extra-articular tissue that begins before 16 years of age [98]. The incidence and prevalence have been estimated as 10 and 65 per 100,000 children, respectively. Patients with unremitting systemic JIA are considered to have the worst prognosis. Severe disease has an effect on bone and joint development, resulting in overgrowth or undergrowth of juxta-articular bone and consequent limb deformities. The macrophage activation syndrome is a potentially life-threatening complication in which there is uncontrolled activation and proliferation of macrophages and T cells, and also a marked increase in serum cytokine levels such as interferon gamma and granulocyte–macrophage colony-stimulating factor (GM-CSF). This complication may occur in 5–8% of patients with systemic JIA, and close monitoring and early treatment are required for the best outcomes. The mortality in this disease is <1% and is mostly in the systemic JIA subtype. One clinical trial of HDIT and autologous HCT in patients with treatment-refractory JIA ($n = 22$) has been reported with a median follow-up of 80 months [40]. Eighteen patients had systemic JIA and four had polyarticular JIA. The HDIT regimen included TBI (400 cGy), cyclophosphamide, and ATG. Early in the clinical trial, two patients developed macrophage activation syndrome less than 1 month after HDIT and died. Precautionary measures added to the treatment may have reduced this risk in later patients. Two other patients died after relapsing and restarting immunosuppressive treatment at more than 1 year after HDIT. Overall and disease-free survival were 82 and 36%, respectively. There were significant improvements in disease activity in the group based on disability and active joint scores. In another study, four of seven patients experienced complete remission for between 5 and 8 years [99]. Two patients progressed within 1 year after transplant and required additional therapy. One patient died within 4 months of starting treatment with disseminated adenovirus infection. In a report from the EBMT registry on 34 JIA patients, 18 (53%) were in complete remission without additional therapy at 12–60 months after HDIT [100]. In a small subset of poor-prognosis JIA patients who fail standard treatment, HDIT and autologous HCT may be of benefit.

Crohn disease

Crohn disease is a relapsing inflammatory disease affecting the gastrointestinal tract with extraintestinal manifestations [101]. In a twin study of Crohn disease in Germany, 35% of the monozygotic pairs had concordance compared with 3% of the dizygotic pairs. There is a genetic association with Crohn disease. Genome-wide association studies have identified 71 susceptibility loci, including NOD2/CARD15. Environmental factors are also considered important for triggering the disease. Associated autoimmune diseases are asthma, type 1 diabetes mellitus, multiple sclerosis, and autoimmune thyroid disease. The goals of treatment are to maintain sustained clinical and endoscopic remissions. Medical therapies include sulfasalazine, prednisone, budesonide, azathioprine, methotrexate, infliximab, adalimumab, and natalizumab. Surgery is not curative and therefore should be considered carefully, but is indicated for management of abscesses, fistulas not responsive to medical therapy, and fibrostenotic strictures with symptoms of small bowel obstruction.

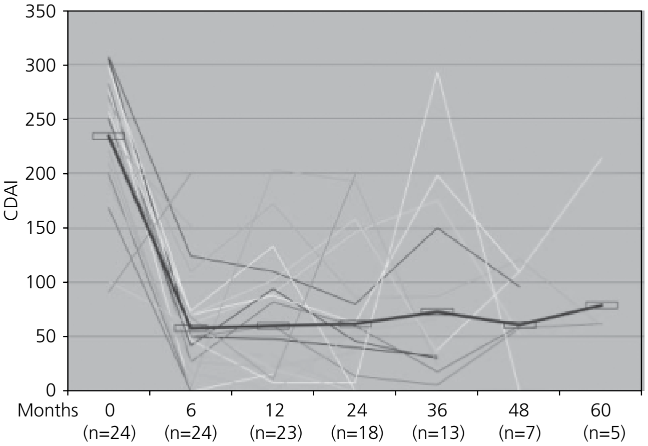

Figure 66.8 Crohn Disease Activity Index (CDAI) pre- and post-HDIT followed by autologous HCT indicates a disease response. The thick line indicates mean CDAI for all patients. There was a significant reduction of Crohn disease activity for as long as 5 years after treatment compared to baseline. Source: Burt et al. 2010 [49]. Reproduced with permission of the American Society of Hematology.

The experience with HDIT followed by autologous HCT has now been reported by several groups. Burt et al. reported the results on 24 patients after high-dose cyclophosphamide and ATG [49]. Eighteen of the 24 patients had follow-up to 5 years after HDIT. Relapse-free survival was 91% at 1 year, 63% at 2 years, 57% at 3 years, 39% at 4 years, and 19% at 5 years (Figure 66.8). The proportion of patients in remission, steroid free, or medication free at any evaluation interval within 5 years after transplant was 70, 80, and 60%, respectively. No treatment-related mortality occurred. In a second study, nine patients with refractory Crohn disease were treated with high-dose cyclophosphamide only [102]. Five of these patients achieved clinical and endoscopic remission but seven of the nine eventually relapsed. After relapse, patients were responsive to low-dose corticosteroids or conventional immunosuppressive therapy. Although responses were substantial, relapses occur with longer follow-up.

Other autoimmune diseases

Investigations of HDIT and autologous HCT have also been conducted in patients with other autoimmune diseases, but experience is more limited. In all these clinical trials, the HDIT regimen was high-dose cyclophosphamide with or without ATG. Six of 14 (43%) patients with refractory chronic thrombocytopenia obtained durable complete responses (platelet count $>100{,}000/\text{mm}^3$), and two patients obtained a partial response at a median of 27 months (range 9–41 months) after HDIT [103]. A clinical trial of HDIT was also performed in patients with recent-onset diabetes mellitus. Fourteen of 15 patients had prolonged periods of insulin independence after HDIT [104]. In a follow-up report, 20 of 23 patients became insulin free. With a median follow-up of 30 months, 12 patients remained insulin free [105]. C-peptide levels increased significantly in both the continuously and the transiently insulin-free groups. The procedure was well tolerated, with minimal adverse events and no treatment-related mortality. The durability of these responses on longer follow-up and the safety of the procedure will determine if this approach could be considered as an acceptable treatment for diabetes mellitus.

Allogeneic hematopoietic cell transplantation for autoimmune diseases: clinical experience

Allogeneic HCT may cure severe autoimmune diseases by replacing the "diseased" autoreactive immune compartment with one that is not autoreactive (although potentially alloreactive). The primary risks of allogeneic HSCT are the morbidity and mortality associated with delayed immune reconstitution and graft-versus-host disease (GVHD). Although the risk of complications and treatment-related mortality is greater than with autologous HCT, there may be a higher potential for sustained remissions of severe autoimmune diseases after allogeneic HCT and therefore improved overall outcome. Survival after allogeneic HCT for non-malignant hematologic disorders or good-risk hematologic malignancies such as chronic myelogenous leukemia in chronic phase has ranged from 85 to 95%. The best outcomes were observed in young patients transplanted from an HLA-matched donor. No clinical trials have yet been conducted of allogeneic HCT for which an autoimmune disease was the primary indication, but a small number of cases have been reported. The largest experience has been in patients with autoimmune cytopenias [106–109]. Of the seven evaluable patients reported from the EBMT registry, five were alive and in remission at a median follow-up of 41 months [106]. One patient with Evans syndrome in the report from the EBMT registry had disease progression and died. The second patient died from treatment-related complications after HCT from an HLA-haploidentical donor. Of the three case reports of Evans syndrome in the literature, one patient relapsed and died and the other two died of transplant-related complications in complete remission [107–109]. There are six cases reported of allogeneic HCT for connective tissue diseases such as SSc, overlap syndrome, and RA [110–114]. Two patients with SSc had high-dose conditioning, one of whom was alive at 5 years in disease remission with resolution of the dermal fibrosis and severe scleroderma. Four patients received reduced-intensity conditioning regimens. All patients were alive at last follow-up and in remission. Three of these patients had stable mixed hematopoietic chimerism and no history of GVHD. The experience from 35 patients with hematologic and non-hematologic autoimmune diseases reported to the EBMT has been summarized [115]. Responses were observed in 78% of patients. Three patients relapsed with the autoimmune disease at a median of 12.3 months after transplant. Treatment-related mortality was 22%. Two deaths occurred from progression of the autoimmune disease. This study was limited by being retrospective and because patients were heterogeneous and data incomplete. Regulatory immune mechanisms associated with the establishment of mixed hematopoietic chimerism may be responsible for inducing remission of the autoimmune disease. Conclusions regarding the therapeutic role of allogeneic HCT for severe autoimmune diseases await the results from prospective clinical trials conducted in a carefully selected group of patients.

Conclusion

The common autoimmune diseases likely result from a genetic predisposition and an environmental trigger. There is a high rate of disease remissions after HDIT and autologous HCT, and a significant proportion are sustained after 4–5 years. The rate and durability of response may depend on the intensity of the HDIT regimen and the type of autoimmune disease being treated. Randomized clinical trials comparing HDIT and autologous HCT with standard therapy or "best clinical practice" are now being conducted in specific autoimmune diseases. The experience with allogeneic HCT as a treatment for autoimmune diseases is still limited but promises to be highly effective. The risks of increased morbidity and mortality from GVHD continue to delay clinical trials of this approach. Carefully selected patients with active autoimmune disease that is life threatening or threatening critical organs and refractory to standard treatment should be considered as candidates for clinical trials of allogeneic HCT or HDIT followed by autologous HCT.

CHAPTER 67

Hematopoietic Cell Transplantation for Rare Hematologic Malignancies

Vinod Pullarkat and Stephen J. Forman
City of Hope Comprehensive Cancer Center, Duarte, CA, USA

Introduction

In this chapter, we review the results of autologous and allogeneic hematopoietic cell transplantation (HCT) for a variety of rare hematologic malignancies that in our opinion would be rarely encountered outside of specialized centers and for which HCT has been performed (Table 67.1). As would be expected with rare disorders, there is paucity of prospective well-designed trials and most published literature is limited to single case reports, small case series, or retrospective analyses that include heterogeneous groups of patients. We have attempted to review the published literature and make recommendations based on the preponderance of evidence. Recognizing the bias towards reporting only positive results that is inherent in single case reports, we have used case series and retrospective analysis of registry data rather than single case reports as the basis for our recommendations whenever possible. It is unlikely that prospective studies to test the role of HCT that contain adequate numbers of patients will ever be performed for the extremely rare entities discussed below. However, there is a need for such trials preferably performed by large cooperative groups for the less uncommon malignancies discussed here.

Rare myeloid malignancies

Langerhans cell histiocytosis

Langerhans cell histiocytosis (LCH) refers to a group of clinical syndromes characterized by clonal Langerhans cell proliferation. These syndromes have historically been designated by different names based on the pattern of organ involvement. These include histiocytosis X, Letterer–Siwe disease, and Hand–Schüller–Christian disease [1]. Although typically a disorder of infants and children, LCH can also occur in adults. Age, pattern of organ system involvement, and organ dysfunction are the most important prognostic factors. In general, children under 2 years of age and adults over 65 years of age do poorly [2–4]. While single-system LCH usually involving the skeleton or skin is an indolent disease, chemotherapy-resistant multisystem LCH (MS-LCH), especially involving organs such as the bone marrow, liver, spleen, and lungs, has an extremely poor prognosis [3, 5].

Various case reports have described successful allogeneic SCT for patients with multisystem LCH [6–10]. One of the first reported that patients who underwent allogeneic HCT for chemotherapy-resistant disease remained in complete remission (CR) 12 years later, showing that long-term disease-free survival (DFS) is possible using this approach [11]. Kudo et al. analyzed the outcome of 15 children with refractory LCH who underwent allogeneic HCT at various institutions in Japan. Ten patients received myeloablative conditioning and reduced-intensity conditioning (RIC) was used in the remaining five. Cord blood was the graft source in 10 patients. The median 10-year overall survival (OS) was 73.3% and was significantly better for patients without risk organ involvement [12]. The French Langerhans Cell Study Group reported results for eight patients with refractory MS-LCH transplanted at six institutions. Three patients underwent autologous HCT and five underwent allogeneic HCT. Of the three patients who underwent autologous HCT, two died of relapse and one was alive and in CR 7 years later. Of the five patients who underwent full-intensity allogeneic HCT, two died of regimen-related toxicity, one died of sepsis 23 months after HCT, and two were alive and in CR 12 years and 21 months, respectively, after HCT, again demonstrating the ability of allogeneic HCT to achieve durable remissions in refractory MS-LCH [13]. The transplant-related mortality of full-intensity allogeneic HCT is high owing to the heavy prior exposure of these patients to chemotherapy and also involvement of vital organs such as the lungs and liver [14]. In an attempt to decrease the treatment-related mortality of allogeneic HCT, Steiner et al. [14] reported the results of reduced-intensity allogeneic HCT using fludarabine-based conditioning in nine pediatric patients with high-risk LCH. Graft sources included matched siblings, matched unrelated donors, mismatched unrelated donors, and haploidentical parental donors. The three patients who underwent haploidentical HCT underwent second transplants for graft failure. After a median follow-up of 390 days, seven of the nine patients were alive without evidence of disease, which is remarkable for this group of heavily treated high-risk patients. The results of multiple reported cases of allogeneic HCT for LCH were summarized by Caselli and Arico [15].

Interestingly, one patient who had engraftment failure with autologous reconstitution after a second allogeneic haploidentical HCT remained in remission 770 days after the first HCT [13], suggesting that autologous HCT may be a viable option for patients who lack suitable donors or are not candidates for allogeneic HCT. Two patients with MS-LCH who underwent successful autologous HCT have been reported. One remained in CR over 4 years and the other at 10 months after HCT [9,16].

Based on the above data and given the poor prognosis of refractory MS-LCH, it seems preferable to perform allogeneic HCT early

Table 67.1 Rare hematologic malignancies for which HCT has been performed

Langerhans cell histiocytosis
Systemic mastocytosis
Hypereosinophilic syndrome
Acute megakaryoblastic leukemia
Acute erythroleukemia
Chronic myelomonocytic leukemia
Adult T-cell leukemia/lymphoma
Natural killer cell leukemia/lymphoma
Mycosis fungoides
Sézary syndrome
Angioimmunoblastic T-cell lymphoma
Primary central nervous system lymphoma
Blastic plasmacytoid dendritic cell neoplasm
Hepatosplenic T-cell lymphoma (gamma/delta T-cell lymphoma)
T-cell prolymphocytic leukemia
Subcutaneous panniculitic T-cell lymphoma

in the course of disease in patients who have matched donors. A higher relapse rate has been observed with RIC compared to full intensity conditioning [15]. Autologous HCT may be an option for patients who lack matched donors. HCT is a promising treatment modality for treatment of MS-LCH and large clinical trials testing both autologous and allogeneic HCT early in the disease course are warranted.

Systemic mastocytosis

Systemic mastocytosis (SM) is characterized by infiltration of the bone marrow and other organs by neoplastic mast cells. Activating mutations in the *KIT* gene (most commonly D816V) are almost invariably present in these neoplastic mast cells. The World Health Organization (WHO) classification recognizes various clinicopathologic SM syndromes, including indolent SM, SM with associated clonal hematologic non-mast-cell lineage disease (SM-AHNMD), aggressive SM, and mast cell leukemia (MCL), among others [1,17]. Aggressive SM and MCL have a dismal prognosis [17,18]. While indolent SM has a prolonged clinical course, as its name suggests, in the case of SM-AHNMD the clinical course is dictated by the underlying malignancy, which most often is acute myeloid leukemia, myelodysplasia, or a myeloproliferative disorder [19,20]. A specific association exists between SM and t(8;21) acute myeloid leukemia (AML) [20–22].

The HCT experience in SM is very limited. Nakamura et al. transplanted three SM patients from human leukocyte antigen (HLA)-identical siblings using non-myeloablative conditioning with fludarabine and cyclophosphamide (CY). One patient had MCL, another had SM with myelodysplasia (SM-AHNMD), and the third had aggressive SM. All patients achieved complete T-cell engraftment. Although there was clinical and pathologic evidence of a graft-versus-mast cell effect, this did not translate into durable remission and all three patients eventually relapsed. In one patient, there was significant morbidity from mast cell mediator release at day +3, concurrent with flare-ups of acute GVHD [23]. In an analysis of 57 patients with SM who had undergone HCT at various centers worldwide, 3-year OS was 74% for patients with SM-AHNMD, 43% for aggressive SM and 17% for MCL. Survival was lower in patients who received RIC compared to full intensity conditioning [24].

Patients with SM-AHNMD fare poorly compared with patients with the underlying hematologic disease alone [19]. This is especially true of cases where the associated hematologic disorder is t(8;21) AML, an otherwise low-risk AML subset. However, this is not surprising given the fact that *KIT* mutations are associated with a poor prognosis in t(8;21)AML [25,26]. Durable remissions have been described in SM-AML with t(8;21) after allogeneic HCT even when recipient bone marrow mast cells carrying t(8;21) were detected 1 year after allogeneic HCT [22,27]. Prolonged remission after a second myeloablative allogeneic HCT has also been reported in a case of SM with t(8;21) AML that relapsed after an initial non-myeloablative sibling donor HCT [21]. In a reported case of SM associated with myelodysplastic syndrome, mast cell infiltration of bone marrow and liver persisted even after normal hematopoiesis was restored by allogeneic HCT. This patient also developed venous thrombosis in the post-transplant period, which was attributed to mast cell mediator release. [28]. Another patient who was alive 6 years after allogeneic HCT for SM with associated chronic myelomonocytic leukemia has also been reported [20].

Given the extremely grim prognosis of patients with aggressive SM and MCL and some evidence of graft-versus-mast cell effect, it appears reasonable to test the efficacy of allogeneic HCT for these subsets of SM, preferably in the context of a clinical trial. Newer kinase inhibitors such as dasatinib are capable of inhibiting the D816V *KIT* mutation may have a role in conjunction with allogeneic HCT [29]. Given the poor chemosensitivity of mast cells, it is possible that more intense conditioning may also be beneficial [21]. Special approaches may be needed to manage morbidity from mediator release during the peritransplant period in patients with a large mast cell burden [23,28].

For patients with SM and t(8;21), it appears that allogeneic HCT in CR1 is the best option if a suitable donor is available based on the limited data available. Recipient-derived bone marrow mastocytosis may persist after allogeneic HCT and does not appear to have clinical significance [22,27]. The efficacy of HCT for SM associated with other hematologic malignancies is unknown at present. It is unlikely that HCT will have a role in indolent SM, especially with the development of targeted therapies that inhibit D816V *KIT* mutation.

Hypereosinophilic syndrome

Hypereosinophilic syndrome (HES) refers to a heterogeneous group of disorders that are characterized by peripheral blood eosinophilia and a propensity to cause organ damage, especially cardiac dysfunction from endomyocardial fibrosis. Criteria for diagnosis of HES have been defined [1,30,31]. Myeloid and lymphocyte variants of HES are now recognized. With the increased understanding of molecular abnormalities underlying myeloid eosinophilic disorders, the majority of these fall under the separate category created in the WHO classification termed Myeloid and lymphoid neoplasms associated with eosinophilia and abnormalities of *PDGFRA, PDGFRB* and *FGFR1* [1]. A subset of patients almost exclusively male with the myeloid variant carry an interstitial deletion resulting in an *FIP1L1–PDGFRA* fusion and are exquisitely sensitive to imatinib, while the lymphocyte variant is associated with clonal T-cell expansion [31–34]. The major cause of morbidity and mortality in HES is cardiac dysfunction [30]. Chronic eosinophilic leukemia-not otherwise specified (CEL-NOS) is classified under myeloproliferative disorders and is characterized by increased bone marrow blasts, clonal eosinophilia, and lack of *PDGFRA/B* or *FGFR1* rearrangement [1].

The results of allogeneic HCT for HES are limited to case reports. Hence the overall results of allogeneic HCT for this disorder cannot be determined. A number of these reports were summarized by Cooper et al. [35]. The majority of transplants have been performed from HLA identical siblings after full-intensity conditioning. A few cases have undergone reduced-intensity or myeloablative conditioning [35,36]. Disease-free survival after up to 6 years of follow-up and reversal of myelofibrosis have been reported [35,37]. Durable remission after allogeneic HCT for a patient with *PDGFRA* rearrangement who manifested with myeloproliferative disease with eosinophilia, T-lymphoblastic lymphoma, and precursor B-cell acute lymphoblastic leukemia has been described [38]. These reports of long-term remission after allogeneic HCT may be suggestive of the curative potential of allogeneic HCT for this disorder.

An interesting observation is that eosinophilia can recur in some cases even when 100% of bone marrow and peripheral blood cells are of donor origin [35,39,40]. This cannot be considered a failure of HCT and usually resolves spontaneously. It is not clear if these cases had the lymphocyte variant of HES with clonal T-cell expansion. High interleukin-5 levels were detected in two patients, which suggests that abnormal T cells may persist in lymphoid organs (despite full donor marrow engraftment) and lead to eosinophilia, which probably resolves with complete donor engraftment in lymphoid organs [35,40].

Our understanding of the biology of HES is rapidly evolving. Newer classifications based on cytogenetic and molecular abnormalities and better definition of prognostic factors may help predict better those patients who are not imatinib responsive and who are more likely to develop end organ damage. The results of imatinib therapy for *FIP1L1–PDGFRA* rearrangement-positive patients is excellent whereas *PDGFRA/B* rearrangement-negative cases rarely have durable responses to imatinib [31,41]. Prognosis for *PDGFRA/B* rearrangement-negative patients who develop end-organ dysfunction is poor and allogeneic HCT should be strongly considered in suitable patients who have early signs of end-organ damage and have failed prednisone and a second-line agent such as hydroxyurea or interferon-α. Although there are reports of improvement in cardiac function after allogeneic HCT in patients with HES and cardiac dysfunction [42], the transplant-related mortality in this situation is likely to be high.

Acute megakaryoblastic leukemia

Acute megakaryoblastic leukemia (AMKL) accounts for about 1% of AML in adults and about 5–10% of AML in children, with a higher incidence in children with Down syndrome [43–45]. The disease has a bimodal age distribution with peaks in early childhood (age under 3 years) and adulthood [44]. Bone marrow fibrosis is a prominent feature of this disorder, making AMKL the most common cause of "acute myelofibrosis" [1,43]. Acute panmyelosis with myelofibrosis (APMF) is a related entity with distinct pathologic features [1]. AMKL may occur de novo or arise from an underlying myeloproliferative or myelodysplastic syndrome. Although 50% of adult patients achieve a CR with convention AML induction chemotherapy, long-term survival rates are dismal with conventional consolidation chemotherapy [43,46–48]. Hence HCT has been used as consolidation therapy in an attempt to improve the outcome.

Single case reports have been published describing reversal of bone marrow fibrosis and durable remissions after allogeneic HCT [49–52] (Figure 67.1). A retrospective analysis of the results of HCT for de novo AMKL in CR1 has been performed by the European Group for Blood and Marrow Transplantation (EBMT). At 3 years after allogeneic HCT, the results in children and adults were, respectively: leukemia-free survival (LFS) 66 and 46%; overall survival (OS) 82 and 43%; and treatment-related mortality (TRM) 0 and 26%. The results of autologous HCT for children and adults were, respectively: LFS 52 and 27%, OS 61 and 30%; and TRM 3 and 8% [53] (Figure 67.2). Athale et al. reported their single-institution experience treating 41 patients with childhood AMKL who included six patients with secondary AMKL and six with Down syndrome. The 2-year event-free survival (EFS) was 26% for allogeneic HCT compared with 0% for chemotherapy alone. The results of allogeneic HCT were significantly better when performed in remission than with persistent disease (2-year EFS: 46% vs. 0%). In both of the above-mentioned studies, the outcomes were better for children with Down syndrome who had an estimated 2-year EFS of 83% in the latter study [47,53].

Based on the above data, allogeneic HCT from matched sibling or matched unrelated donors should be the consolidation treatment of choice in adults with AMKL who achieve CR. In children, autologous transplant in CR1 is an option in patients who lack a matched sibling donor and there are reports of prolonged survival after this approach. The outcome of autologous transplant in adults is very poor. At present, allogeneic HCT cannot be recommended for patients with resistant disease, who should be treated with investigational approaches. There appears to be no advantage for allogeneic HCT over autologous HCT in patients with Down syndrome and AMKL. Sufficient data are not available to determine efficacy of HCT for APMF.

Acute erythroleukemia

Acute erythroleukemia (AEL) is an uncommon form of AML, accounting for about 4.5% of all AMLs [54]. AEL may occur de novo or secondary to an underlying myelodysplastic or myeloproliferative disorder or after previous chemotherapy [55,56]. AEL has a poor prognosis compared with other AML subtypes, with a median overall survival of only 9 months in one retrospective study [56]. Like AMKL, AEL has a dismal prognosis with conventional chemotherapy [56,57].

The EBMT have reported the results of 103 autologous and 104 HLA-identical sibling allogeneic HCTs performed for de novo AEL in CR1. For allogeneic HCT, the 5-year LFS, relapse incidence and TRM were 57± 5, 21 ± 5, and 27 ± 5%, respectively, and the corresponding figures for autologous HCT were 26 ± 5, 70 ± 6, and 13 ± 4%, respectively. In multivariate analysis, age remained the most important prognostic factor for both allogeneic and autologous HCT [58]. In a smaller study, Killick et al. reported the outcome of 27 patients with AEL, who included eight adults with secondary AEL and five children. Among patients with de novo AEL, 95% achieved CR with induction chemotherapy compared with only 57% of patients with secondary AEL. Eighteen of 22 patients (82%) achieving CR underwent consolidation by HCT (15 allogeneic, three autologous). The median survival of 2.9 years for de novo AEL was not different from that of their matched controls with other forms of AML. The overall relapse rate of only 35% suggests a benefit for HCT consolidation in CR1 [59].

Hence allogeneic HCT is currently the treatment of choice for patients with AEL who are in CR1. Autologous HCT may be an option for patients in CR1 who lack matched donors. The results of allogeneic HCT for refractory and relapsed disease remain unknown at present.

Chronic myelomonocytic leukemia

Chronic myelomonocytic leukemia (CMML) is clonal stem-cell disorder characterized by peripheral blood monocytosis and shares features with both myelodysplastic and myeloproliferative disorders. The median age at diagnosis is 65–75 years, with a male predominance. Criteria for diagnosis of CMML have been defined in the WHO classification [1]. Since CMML was previously grouped with the myelodysplastic syndromes, patients who underwent allogeneic HCT for CMML were included in reports of HCT results for myelodysplastic syndromes. However, CMML has distinct clinicopathologic features that warrant its consideration as a separate entity.

Although CMML includes a heterogeneous group of patients with varying rates of disease progression, the overall prognosis is poor, with a median survival of only 12 months in one study [60]. CMML is not curable with conventional chemotherapy and the response to targeted therapies is poor except in the small subset of patients who carry a *PDGFRB* fusion oncogene and are sensitive to imatinib [61]. Recognizing this dismal prognosis, allogeneic HCT has been tried as a potential curative option.

In the largest experience reported of patients who have undergone HCT for CMML, Eissa et al. at the Fred Hutchinson Cancer Research Center analyzed the outcome of 85 patients who underwent allogeneic HCT between 1986 and 2008. The median age of patients was 51.7 years and they received a variety of conditioning regimens. Thirty-eight patients underwent matched related donor HCT and 47 matched unrelated donor HCT. Progression-free survival (PFS) was 38% at 10 years and relapse incidence was 27% at 10 years. The significant risk factors for increased mortality were high-risk cytogenetics, high HCT Comorbidity Index and higher age [62] (Figure 67.3). The EBMT reported the outcome of 50 patients who underwent allogeneic HCT for CMML. Forty-three patients received transplants from related donors and seven received unrelated donor transplants. The median age of the patients was 44 years. Conditioning was total body irradiation (TBI) based in 26 patients and chemotherapy based in the remainder. After a median follow-up of 40 months, the 5-year estimated OS, DFS, and probability of relapse were 21, 18, and 49%, respectively [63]. A retrospective analysis of the outcomes of 73 patients with CMML reported to the French Registry (SFGM-TC) between 1992 and 2009 showed a 3-year OS, NRM, EFS and cumulative incidence of relapse of 32%, 36%, 29% and 35% respectively [64]. Allogeneic HCT for CMML has been reviewed by Cheng et al. [65].

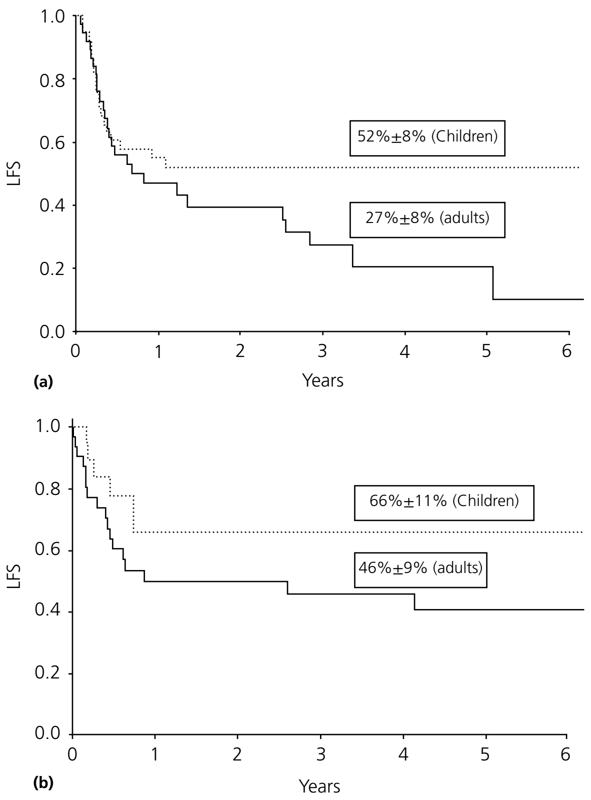

Figure 67.2 (a) Leukemia-free survival (LFS) after autologous HCT in adults and children with de novo AMKL in CR1. (b) LFS after allogeneic HCT in adults and children with de novo AMKL in CR1. Source: data from Garderet et al. 2005 [53].

Allogeneic HCT from matched siblings or matched unrelated donors should be an early consideration for patients with CMML who are suitable candidates. It must be noted that although the median age of patients in the above studies was much lower than the median age at diagnosis of CMML patients as a whole, the TRM for allogeneic HCT is fairly high. Comorbidity is a strong predictor of outcome and must be an important consideration in selecting patients for allogeneic HCT. The majority of reported patients have undergone full-intensity conditioning, which most likely contributed to the high TRM. Hence allogeneic HCT with RIC needs to be explored further as a curative option in CMML.

Rare lymphoid malignancies

Adult T-cell leukemia/lymphoma

Adult T-cell leukemia/lymphoma (ATLL) refers to a specific clinicopathologic syndrome characterized by prominent skin involvement, hypercalcemia, and an acute leukemic or lymphomatous presentation. ATLL is specifically associated with infection with type I human T-cell lymphotropic retrovirus (HTLV-I), which is clonally integrated into the genome of the malignant T cells [1]. Although ATLL is endemic in parts of Japan and the Caribbean, cases also occur in the United States, especially in the south-east [1,66]. Chronic and smoldering forms of the disease do occur and have a more indolent course compared with the acute or lymphomatous types [1,67].

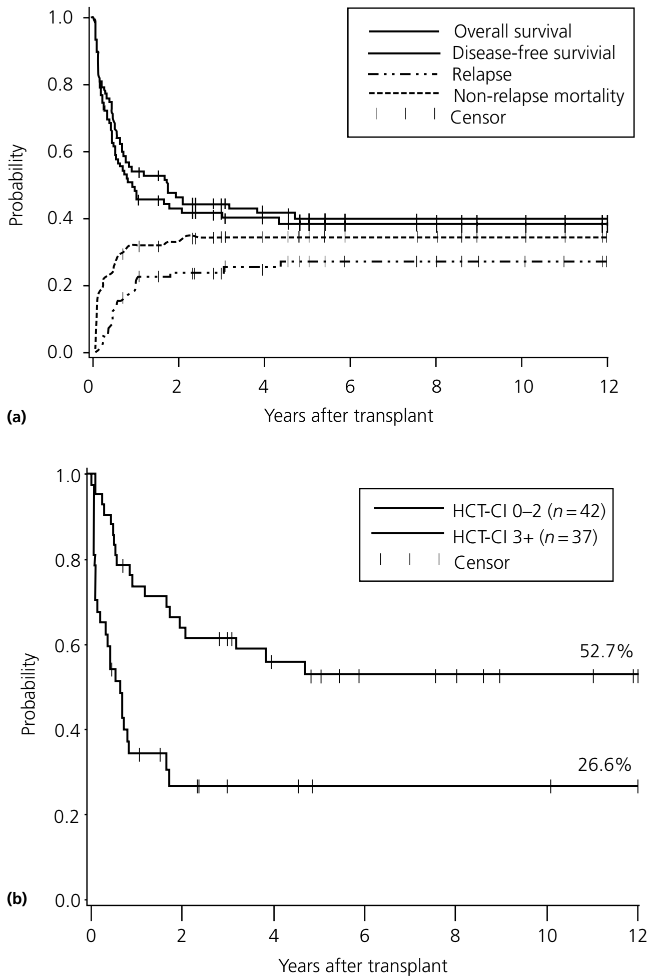

Figure 67.3 (a) Survival, relapse, and NRM for 85 patients with CMML who have undergone allogeneic HCT. (b) Probability of survival according to the hematopoietic cell transplantation-specific comorbidity index. Source: Eissa et al. 2011 [62]. Reproduced with permission of Elsevier.

Not surprisingly, most of the experience in treating ATLL comes from Japan. The results of intensive combination chemotherapy are poor, as are results of autologous HCT [68,69]. Increased use of allogeneic HCT has been implicated in the decreasing trend in mortality observed in Japan [70]. Reported studies of HCT for ATLL were summarized by Jabbour et al. [71]. In one of the initial case series, Fukushima et al. reported results for 40 patients with acute or lymphomatous types of ATLL who underwent allogeneic HCT at seven institutions in Japan [72]. All but one patient received myeloablative conditioning. Twenty-seven patients were transplanted from matched related donors, five from mismatched related donors and eight from matched unrelated donors. Of the 36 donors whose HTLV-1 status was known, nine were HTLV-1 positive. The estimated 3-year overall survival, relapse-free survival, and disease relapse were 45.3, 33.8, and 39.3%, respectively (Figure 67.4). Of 10 patients who relapsed, three were able to achieve remission by reduction in immunosuppression, suggesting a graft-versus-leukemia/lymphoma effect [72]. In the largest retrospective series of allogeneic HCT for ATLL reported to date, among 586 patients who underwent HCT using bone marrow or peripheral blood stem cells at various institutions in Japan, the

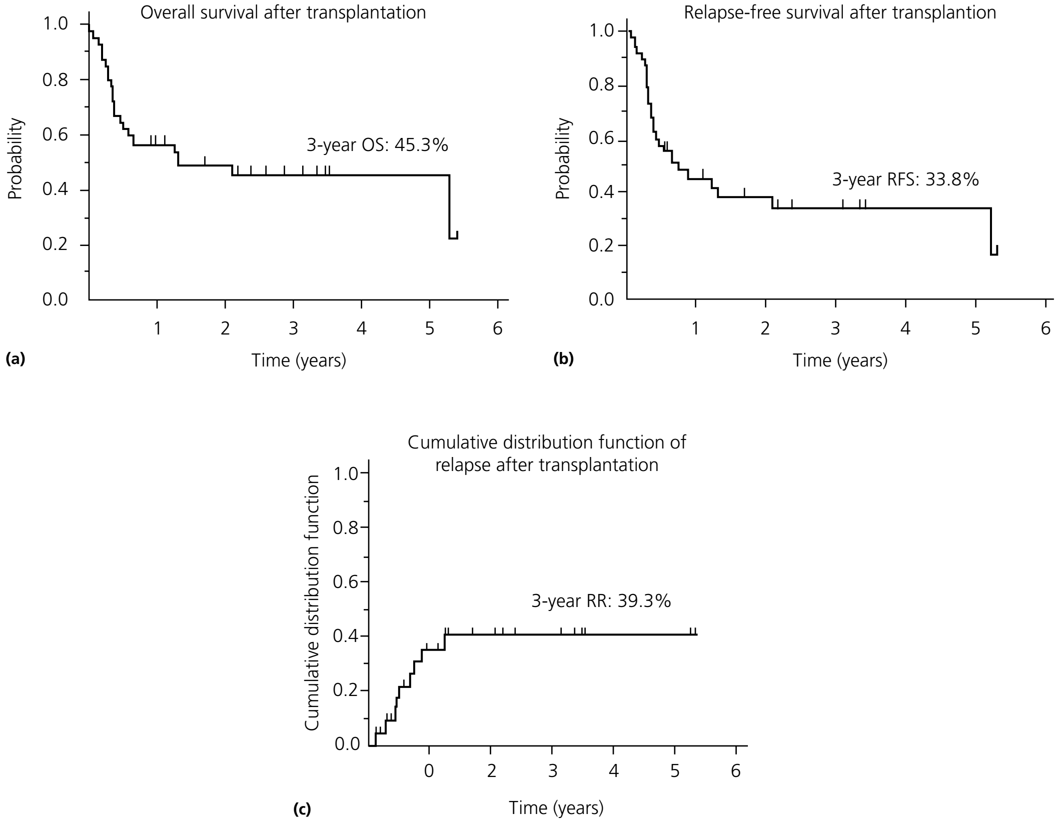

Figure 67.4 (a) Estimated 3-year overall survival of 40 patients who underwent allogeneic HCT for ATLL. (b) Estimated 3-year relapse-free survival. (c) Estimated 3-year relapse risk. Source: Fukushima et al. 2005 [72]. Reproduced with permission of Nature Publishing Group. Copyright 2005.

3-year OS was 36%. The 3-year OS rates were 39 and 34% for patients who underwent myeloablative conditioning and RIC, respectively. In multivariate analysis, factors contributing to poorer OS were older age, male gender, active disease, poor performance status, and use of unrelated donors. No significant difference in OS between myeloablative conditioning and RIC was observed. Among the 174 recipients of cord blood transplants included in this report, the 3-year OS was only 21% [73]. For patients not in CR at time of allogeneic HCT, a higher serum soluble interleukin-2 receptor level was associated with poor outcome [74]. Allogeneic HCT is the only currently available therapy for ATLL that offers any prospect of long-term survival.

Disease relapse/progression and TRM remain major obstacles to improving allogeneic HCT results for ATLL. The Nagasaki Transplant Group recently published the outcome of 35 patients who experienced relapse or disease progression after allogeneic HCT [75]. Complete remissions were achieved in seven patients by either withdrawing immunosuppression or by use of DLI in combination with cytoreductive therapy. DLI-induced remissions were durable and the 3-year OS for these patients was 19.3%. Similar results have been observed in other reports, suggesting that strategies to augment graft-versus-leukemia/lymphoma effect are likely to improve HCT outcome further. Attempts to improve HCT outcome by reducing the conditioning intensity have yielded only limited success. Even with RIC, TRM at 1 year was 29.2% in the large Japanese series compared with 32.7% for myeloablative conditioning [73]. The profound immunosuppression of ATLL patients prior to HCT is most likely the major contributor to the high TRM. For instance, in one report the cytomegalovirus reactivation rate was as high as 83% [71].

Donor-derived ATLL has been reported in a patient who underwent allogeneic HSCT from his HLA-matched brother who was an HTLV-1 carrier [76]. Using a tumor-specific polymerase chain reaction technique, it was later shown that the relapse originated from donor T cells that were already infected in the donor [77]. Thus, the immunosuppression of the recipient appears to have facilitated the transformation of HTLV-1-infected donor T cells to frank T-cell leukemia/lymphoma. The precise incidence of donor-derived relapse is not known and therefore it not clear at present if HTLV-1 seronegative unrelated donors should be preferred over seropositive matched siblings. Use of unrelated donors, however, was associated with poorer overall survival in multivariate analysis.

An interesting aspect of allogeneic HCT for ATLL has been the observation of viral clearance after allogeneic HCT in recipients who have received grafts from seropositive or seronegative donors [78]. This is likely to be mediated by donor-derived cytotoxic T-cell response to viral epitopes resulting in viral clearance.

Natural killer cell neoplasms

Natural killer (NK) cell neoplasms include the extranodal NK/T-cell lymphoma, nasal type, and aggressive NK-cell leukemia subtypes described in the WHO classification. Extranodal NK/T-cell lymphomas have a predilection to arise in the upper aerodigestive tract, but may also involve other sites such as the skin, gastrointestinal tract, and testes. Cases with disseminated disease often have significant comorbidity from cytokine-mediated phenomena such as hepatic dysfunction and hemophagocytic syndrome. Rare cases may have a cytotoxic T-cell phenotype and hence the designation NK/T-cell lymphoma. NK-cell neoplasms are strongly associated with Epstein-Barr virus (EBV), which may have a role in their pathogenesis. There is marked geographic variation in the incidence of NK-cell neoplasms due to their strong predilection for Asians and indigenous populations of Mexico and Central and South America [1,79]. The entity previously termed blastic NK-cell lymphoma ($CD4^+56^+$ hematodermic neoplasm) is now known to be a malignancy of plasmacytoid dendritic cells and therefore is not a true NK-cell neoplasm [1].

In the case of extranodal NK/T-cell lymphoma, only about one-third of patients with localized disease are long-term survivors with the conventional approach of radiation and combination chemotherapy [80]. Locoregional and systemic failures are common and patients with relapsed disease or systemic disease at presentation have a dismal outcome [81,82]. The prognosis is even worse for aggressive NK leukemia, with a median survival of only 2 months in one study [83]. Hence there has been interest in using HCT to improve the poor outcome of NK-cell neoplasms.

Despite not being an extremely rare neoplasm in some geographic areas, systematic prospective trials to evaluate the efficacy of HCT for NK-cell neoplasms have not been performed. Anecdotal reports describe success with autologous and allogeneic HCT even for advanced disseminated disease [84–88]. Au et al. reported their experience with 18 consecutive cases of nasal type NK/T-cell lymphoma treated at two institutions in Hong Kong. Eight cases were treated in CR1, five in CR2, and five with refractory disease. Five patients had extranasal disease before autologous HCT. The most common initial treatment used was combination chemotherapy and radiotherapy. Two patients died of treatment-related causes, nine patients relapsed, and seven remained in CR. All patients with active or disseminated disease at the time of HCT died early of relapse or disease progression. The actuarial survival for the whole cohort was 39% after 6 months. Disease relapse beyond 6 months was not seen [89]. Lee et al. compared the outcome of 47 patients (from three published series) who underwent autologous HCT with that of 107 historical controls matched for prognostic risk group and disease status at HCT. Autologous HCT conferred a significant survival advantage for patients who were transplanted in CR (5-year disease-specific survival of 87.3% for the HCT vs. 67.8% for the non-HCT group) [90]. For patients with localized disease (Stage I/II), autologous HCT should not be performed outside a clinical trial. Autologous HCT should be reserved for patients with advanced disease who are in CR after initial chemotherapy. Improvements in chemotherapy, particularly with the use of combinations including L-asparaginase, have enhanced the ability to achieve CR even in relapsed/refractory disease and have enabled more patients to proceed to HCT. In one study including patients with advanced/relapsed/refractory disease, autologous HCT performed after two cycles of SMILE (dexamethasone, methotrexate, ifosfamide, L-asparaginase, etoposide) chemotherapy appeared superior to allogeneic HCT or continued chemotherapy, but the difference was not statistically significant [91]. Since long-term DFS is possible with asparaginase-containing regimens in a subset of patients even with advanced disease, further investigations to identify candidates who would benefit from autologous HCT are critical. The EBV-DNA level in peripheral blood has been shown to be a marker of disease burden and may prove to be useful in monitoring response to chemotherapy and selecting patients for autologous HCT in CR1 [92].

Murashige et al. reported allogeneic HCT results for 28 patients with NK-cell neoplasms [93]. The majority ($n = 22$) had extranodal NK/T-cell lymphoma. Twelve patients were chemosensitive and 16 were chemorefractory at the time of transplant. Twenty-three patients received grafts from matched related donors and 23 underwent myeloablative conditioning. With a median follow-up of 34 months, the 2-year PFS and OS were 34 and 40%, respectively (Figure 67.5). Patients who did not relapse within 10 months after HCT remained free of disease. In multivariate analysis, stem-cell source (bone marrow versus peripheral blood) and histology (extranodal NK/T-cell lymphoma versus others) were risk factors for PFS (relative risk 3.03 and 3.94, respectively). These results are good considering that 19 of the 28 patients had active disease at the time of HCT [93]. A similar OS rate was seen for 12 patients with NK-cell lymphoma who underwent unrelated donor HCT through the Japan Marrow Donor Program [94] and also in other case series [95,96].

The results and the ability to undergo allogeneic HCT may further improve with advances in initial chemotherapy, particularly with the use of L-asparaginase-containing regimens. In the study by Yamaguchi et al., among advanced/refractor/relapsed patients a CR

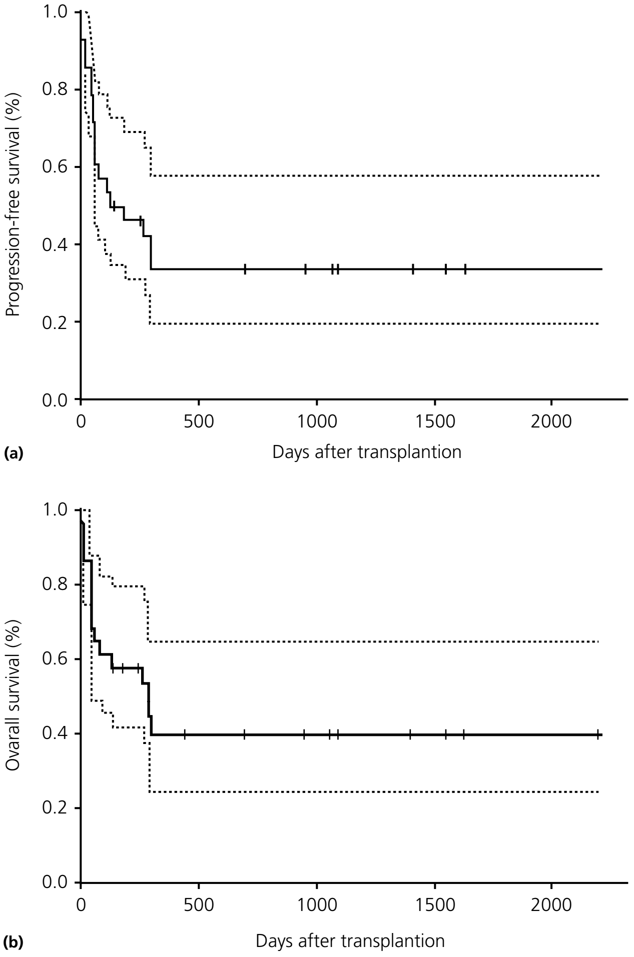

Figure 67.5 (a) Progression-free survival (PFS) and (b) overall survival (OS) of 28 patients with NK-cell neoplasms who underwent allogeneic HCT. PFS was 34% and OS was 40% at 2 years. Median follow-up was 34 months. Broken lines indicate 95% confidence intervals. Source: Murashige et al. 2005 [93]. Reproduced with permission of John Wiley & Sons, Ltd.

rate of 45% was achieved after two cycles. Among 28 patients who completed two cycles of SMILE chemotherapy, 17 were able to undergo allogeneic HCT with a 1-year OS and PFS of 59% [91]. This was not statistically different from the results for patients who underwent autologous HCT or chemotherapy. No conclusions about the efficacy of the RIC approach can be drawn based on available data.

Based on the above evidence, for extranodal NK/- cell lymphoma with advanced stage disease, autologous HCT should be considered as consolidation therapy for patients who enter CR after chemotherapy. Long-term survival has been reported with this approach and TRM is expected to be low. Autologous HCT has no role in refractory nasal-type extranodal NK/T lymphoma or aggressive NK-cell leukemia, and these patients should be strongly considered for allogeneic HCT since this is the only therapy known to result in long-term survival in this group of patients. In the case of systemic NK-cell neoplasms, the major obstacle to allogeneic HCT appears to be the comorbidity from paraneoplastic phenomena such as hepatic dysfunction. Therefore, better strategies for the initial management are needed to realize the full curative potential of allogeneic HCT. Existence of a graft-versus-leukemia (GVL) effect after allogeneic HCT has been suggested [84]. Monitoring EBV-DNA in peripheral blood may allow better selection of patients for HCT and also monitoring of minimal residual disease after HCT.

Mycosis fungoides and Sézary syndrome

Mycosis fungoides (MF), the commonest form of cutaneous T-cell lymphoma, is a neoplasm of $CD4^+$ T-cells that home to the skin. Initial stages of MF are characterized by patch or plaque lesions and typically last for many years. In the late stages, patients develop skin tumors and extracutaneous dissemination to lymph nodes and visceral organs [1,97,98]. Although patients with early stages of MF often respond to current therapies that include retinoids, interferon-α, photopheresis, monoclonal antibodies, and chemotherapy, among others, these therapies have no curative potential and the disease ultimately progresses to its more advanced stages [98]. In one study, the median survival of Stage IV patients was only 13 months from initiation of therapy [99]. Sézary syndrome (SS) is an aggressive variant of MF and is characterized by erythroderma, lymphadenopathy, circulating neoplastic T cells, and a much more aggressive clinical course [1,97,98].

From the limited experience available, it can be concluded that autologous HCT is not capable of inducing durable remissions when performed in the advanced stages of MF in heavily pretreated patients. In a series of 20 patients compiled by Duarte et al., although a CR rate of 90% was achieved with autologous HCT, the 1-year OS was only 50% and time to progression was only 2.3 months [100]. Similarly, lack of benefit for autologous HCT was also evident in a meta-analysis [101]. T-cell depletion of the graft had no effect in improving the dismal outcome of autologous HCT [100,102]. Whether autologous HCT early in disease course, possibly in combination with post-transplant maintenance therapy with currently available active agents, will produce durable remissions remains to be determined.

Given the grim prognosis of patients with advanced stage MF and SS, allogeneic HCT has been attempted to harness a potential GVL effect. Molina et al. first reported the results for a series of eight patients treated at the City of Hope Medical Center with allogeneic HCT [103]. Three patients had tumor stage MF, one had erythrodermic MF, and the remaining three had SS. All patients were heavily pretreated and had failed a median of seven previous therapies. Graft source was from a matched sibling in four patients and a matched unrelated donor in the other four. Conditioning regimens were fractionated total body irradiation (FTBI)/CY (three patients), BU/CY (one patient), and fludarabine/melphalan (four patients). All patients achieved CR and their original T-cell clones disappeared from blood by 60 days after HCT. Although two patients had new T-cell clones detectable in the peripheral blood on follow-up analysis, these did not have any clinical impact and these patients remained disease-free. With a median follow-up of 56 months, six patients remained disease free [103] (Figure 67.6). A subsequent report from the same institution of fludarabine and melphalan (reduced-intensity) conditioned allogeneic HCT showed a 2-year PFS of 45% and a non-relapse mortality (NRM) of 27% among 11 patients [104].

Other larger case series of allogeneic HCT for MF and SS have subsequently been reported. Duarte et al. described a retrospective analysis of 60 patients (MF = 36, SS = 24) who underwent allogeneic HCT at EBMT centers. The 1- and 3-year OS was 66 and 54% and PFS was 42 and 34%, respectively (Figure 67.7). RIC resulted in a significantly lower NRM than myeloablative conditioning (1-year NRM 14% vs. 38%, respectively) without increasing relapse risk. T-cell depletion increased relapse risk. Better PFS was observed in recipients of matched related donor grafts than matched unrelated donor grafts [105]. A recent report on the long term outcome of this cohort showed an OS of 44% and PFS of 30% at 7 years. Relapse/progression occurred in 45%. Median time of relapse was 3.8 months and only 2 relapses occurred beyond 2 years after HCT [106]. Results of allogeneic HCT for CTCL were summarized by Schlaak et al. [107].

Collectively, these reports provide evidence for the feasibility and curative potential of allogeneic HCT even in this group of advanced-stage, high-risk patients. RIC regimens appear to be better tolerated and result in lower NRM. Clear evidence of a potent GVL effect has been demonstrated in MF by the regression of persistent lesions by withdrawal of immunosuppression or DLI [106]. Infection appears to be a major contributor to NRM, no doubt resulting from extensive prior use of therapies with profound immunosuppressive effects. In the light of the substantial impact of MF on quality of life and the inability of current treatments to prevent progression, consideration should be given to allogeneic HCT after failure of two or three initial therapies, at least in patients who are under 60 years of age and have matched sibling donors.

Angioimmunoblastic T-cell lymphoma

Angioimmunoblastic T-cell lymphoma (AITL) is a rare lymphoma accounting for 1–2% of non-Hodgkin lymphomas. AITL is strongly associated with EBV, which can be detected within the B cells in involved tissues in the majority of cases. Systemic symptoms, skin rash, immunodeficiency and autoimmune phenomena such as hemolytic anemia are characteristic features of AITL. Patients with AITL are usually middle-aged or elderly and often present with advanced disease. Although anecdotal reports describe responses to a variety of agents, including immunosuppressants, biologic response modifiers, and chemotherapeutic agents, the overall prognosis for AITL is poor [1,108,109]. In one study that analyzed the outcome of 33 patients treated with chemotherapy, the OS at 5 years was 36%. Notably, two of the long-term survivors in this study had received autologous HCT [110].

Although some patients with AITL have been included in various reports of HCT for T-cell lymphomas, two reports that have analyzed the outcome of autologous HCT for AITL as a separate cohort

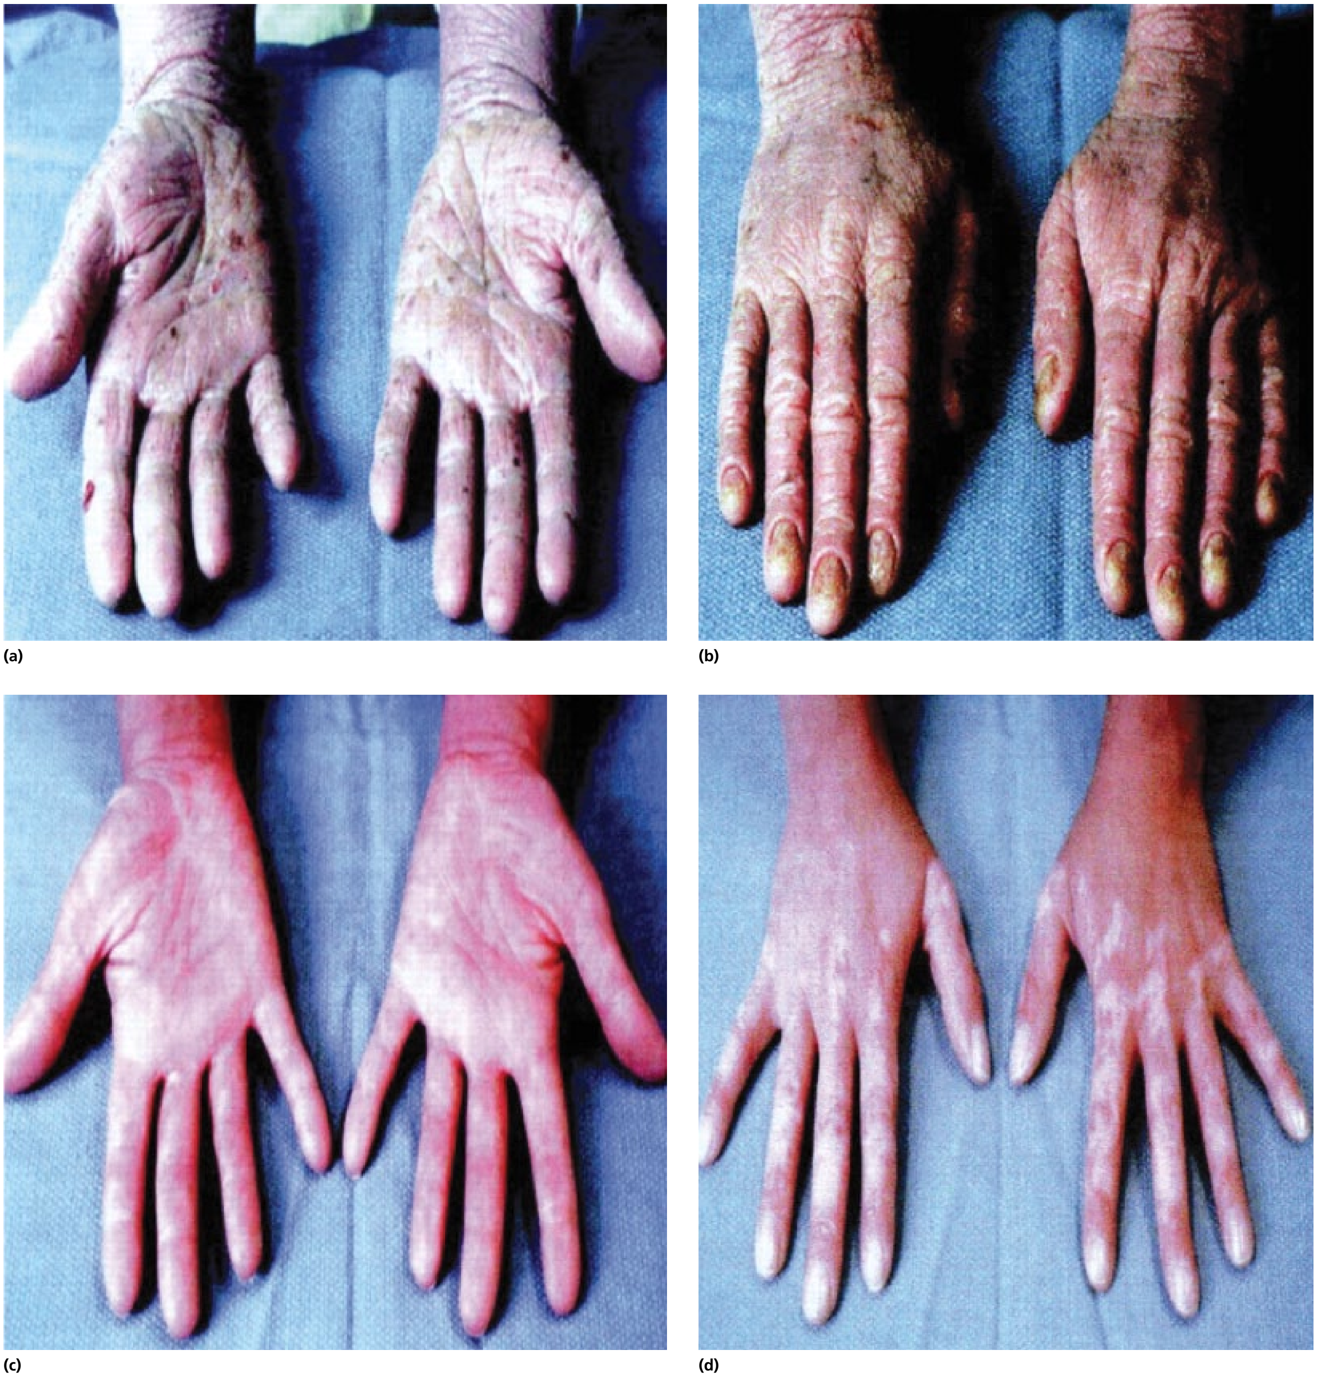

Figure 67.6 (a, b) Hands of a patient with Sézary syndrome shows fissuring, cracking, and nail destruction. (c, d) One year after allogeneic HCT, there is regression of skin involvement and normalization of the nails. Source: Molina et al. 2005 [103] Reproduced with permission of the American Society of Clinical Oncology.

are discussed here. In the first of these reports, from the EBMT, 146 patients with AITL underwent autologous HCT; the majority with BEAM [BCNU, etoposide, Ara-C (cytosine arabinoside), melphalan] conditioning. NRM was 7% at 24 months and actuarial OS was 59% at 48 months. The cumulative incidence of relapse was estimated at 51% at 48 months. Disease status at HCT was the major factor that determined outcome. The PFS rate for patients who underwent HCT in CR was 56% at 48 months as opposed to 23% for patients with chemotherapy-refractory disease [111]. Given the poor outcome with conventional chemotherapy, these results would justify performing autologous HCT in CR1 for AITL.

In another report, the Spanish Lymphoma/Autologous Bone Marrow Transplant Study Group analyzed the outcome of 19 patients who underwent autologous HCT. Again, the median age of 46 years of these patients is low for AITL. Eleven patients were in a first or later CR. Fifteen patients (79%) achieved CR after HCT. The OS and PFS at 3 years were 60 and 55%, respectively, for the whole group (Figure 67.8). Predictably, bone marrow involvement,

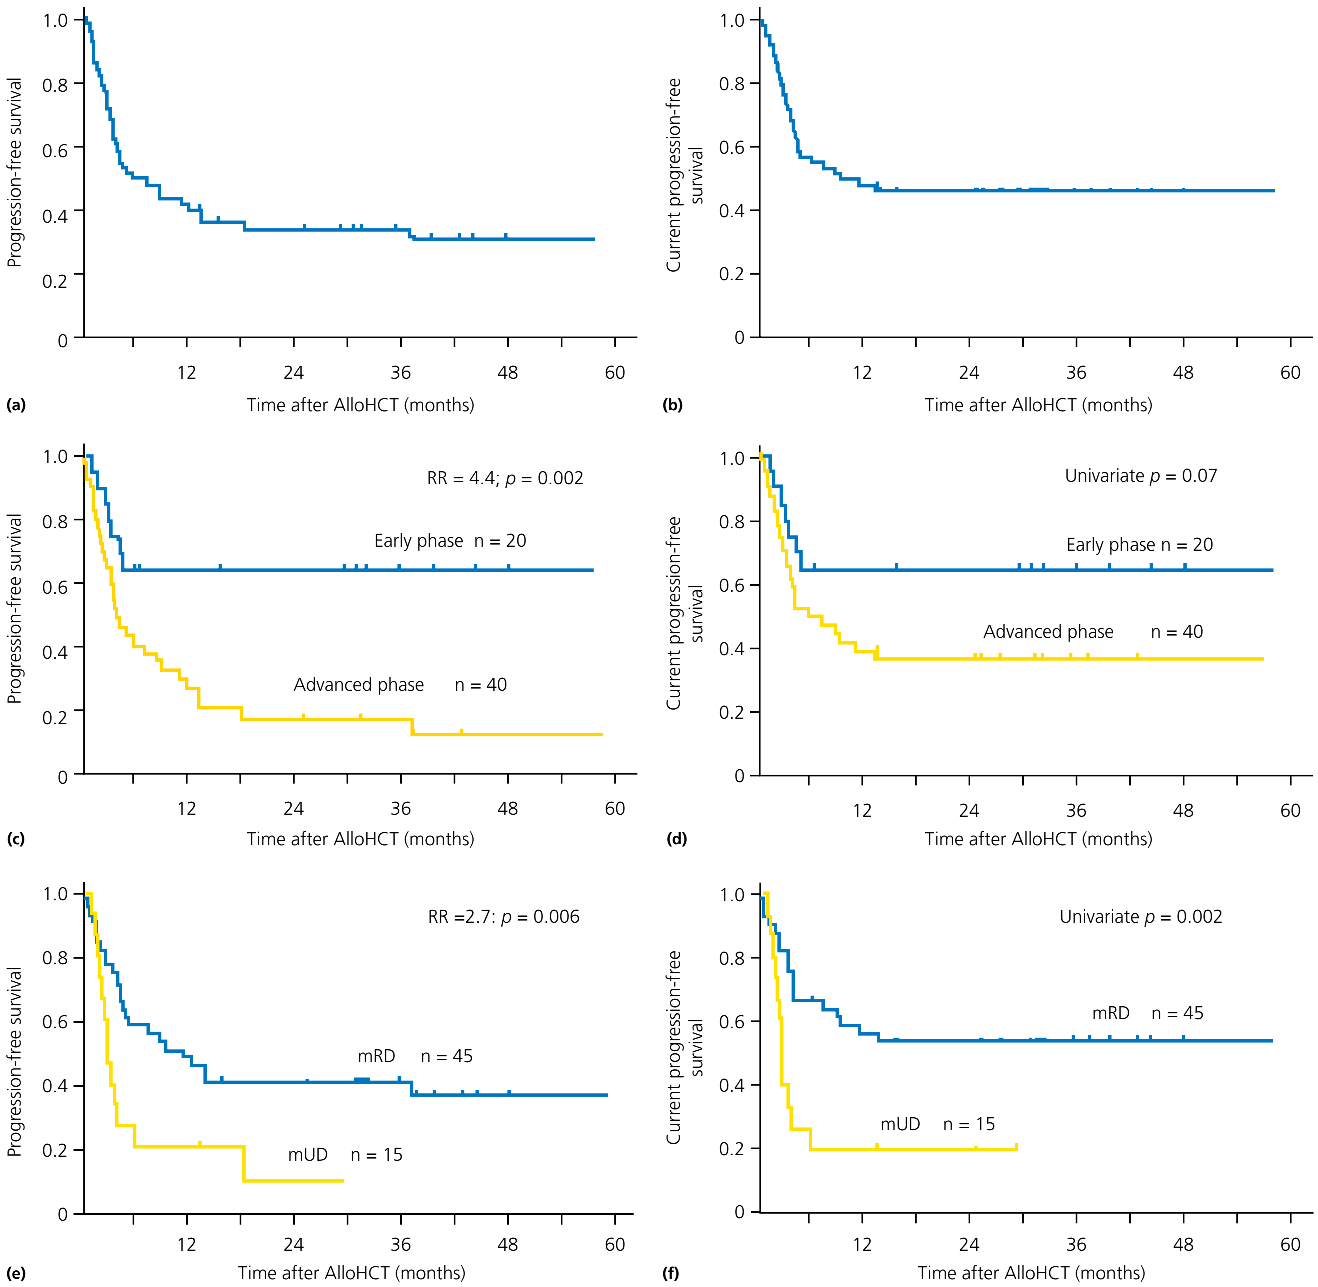

Figure 67.7 Probability of PFS (a, c, e) and current PFS (b, d, f) for 60 patients with mycosis fungoides and Sézary syndrome. Source: data from Duarte et al. 2010 [105].

refractory disease, and more than one factor of the age-adjusted International Prognostic Index (IPI) were associated with poor outcome [112]. Although the above two studies undoubtedly represent a selected group of patients who were able to undergo autologous HCT, the results appear to compare favorably with those of conventional therapy. Patients with AITL are at risk for EBV-positive and also EBV-negative secondary B-cell lymphomas [113,114]. Both EBV-positive and -negative lymphoproliferative disorders can occur after autologous HCT and these appear to respond to rituximab-based therapy [115,116].

The allogeneic HCT experience in AITL has been reported in a retrospective study from EBMT centers. Results for 45 patients with a median age of 48 years were reported. Eleven patients failed autologous HCT. Twenty patients received RIC. NRM was 25% at 1 year and the relapse rate was 20% at 3 years. Relapses were less common in patients with chronic GVHD, suggesting a GVL effect in this disease. PFS and OS were 66 and 64%, respectively, at 3 years and were significantly better in chemotherapy-sensitive patients [117]. The advanced age of patients with AITL and the significant tumor-associated comorbidities are significant hurdles for successful allogeneic HCT. However, allogeneic HCT should be considered in suitable patients who have primary or relapsed refractory disease, since these patients do not benefit from autologous HCT.

Primary central nervous system lymphoma

Primary central nervous system lymphoma (PCNSL) comprises about 1–2% of NHL cases. Its incidence is rising in both immunocompromised and immunocompetent individuals [118]. PCNSL typically presents as unifocal or multifocal periventricular parenchymal masses. Ocular involvement, either clinical or asymptomatic, may be present in 10–20% of patients at diagnosis. Other systemic involvement is extremely rare at presentation. The median age at diagnosis is 60 years. Over 90% of PCNSLs have a diffuse large B-cell histology and 2–4% of cases are of T-cell origin. Unlike the situation with immunocompromised patients, EBV does not play a role in the pathogenesis of PCNSL in immunocompetent patients [1,119].

Although data from randomized trials are lacking, current therapy for PCNSL involves chemotherapy with high-dose methotrexate alone or in combination followed by whole-brain radiotherapy (WBRT). The long-term outcome of PCNSL is poor. Although 2-year PFS of 57% and OS of 67% were reported in one study [120], the 10-year OS of patients under 60 years of age in another trial was only 32% [121]. Notably, in the latter trial, there were no long-term survivors among patients who were over 60 years of age at diagnosis. Neurotoxicity resulting from WBRT and chemotherapy is a major cause of morbidity in survivors, especially in those above 50 years of age, who comprises the majority of PCNSL patients [122]. Therefore, high-dose chemotherapy with autologous stem-cell support after initial chemotherapy has been tried as a strategy to minimize neurotoxicity by eliminating or reducing WBRT dose and improve the long-term outcome in PCNSL.

The small sizes of reported studies and the marked variations in the initial and high-dose chemotherapy regimens make it difficult to draw firm conclusions regarding the efficacy of the autologous HCT approach as front-line therapy of PCNSL. In general, in these studies chemotherapeutic agents for conditioning were selected based on their ability to cross the blood–brain barrier. Illerhaus et al. reported results for 30 patients younger than 65 years of age with PCNSL who were enrolled in a trial of initial chemotherapy with three cycles of high-dose methotrexate (MTX) followed by a cycle of cytarabine and thioTEPA (*N*-triethylenethiophosphoramide), following which peripheral blood stem cells were collected. High-dose therapy consisted of carmustine and thioTEPA. Fractionated radiotherapy (45 Gy, two doses of 1 Gy/day) was given as consolidation. Twenty-three patients were able to undergo autologous HCT, 15 of whom achieved CR and eight achieved partial remission (PR). All 21 patients who underwent WBRT achieved CR. With a median follow-up of 63 months, the 5-year OS probability was 69% for the whole group and 87% for patients who received HCT. Leukoencephalopathy developed in 17% of patients, all of whom had received WBRT [123]. In another Phase II study, Colombat et al. treated 25 patients below 60 years of age with two cycles of high-dose MTX-based chemotherapy. Seventeen responding patients then received high-dose therapy with BEAM and autologous HCT followed by 30 Gy of WBRT. With a median follow-up of 34 months, the estimated 4-year OS and EFS were 64 and 46% respectively. Although the follow up was short, no leukoencephalopathy had developed in evaluable patients who received the whole planned therapy [124]. In another small study of six patients treated with the same regimen as in the above study, four patients were alive without evidence of disease with a median follow-up of 41.5 months [125]. Other studies have utilized a response-adapted WBRT approach restricting radiation therapy to patients who fail to achieve CR after HCT. Yoon et al. reported on 11 patients who underwent autologous HCT with busulfan, cyclophosphamide, and etoposide conditioning after initial therapy with high-dose MTX and cytarabine. Only two patients who failed to achieve CR after HCT received WBRT. Six patients had relapsed and the median EFS was 15 months, with 2-year EFS and OS of 30.3 and 88.9%, respectively [126]. In another study, among 13 patients treated with MTX and cytarabine /thioTEPA, 11 underwent HCT. Only three of four patients with PR after HCT received WBRT. The 3-year DFS and OS were 76.9% and were similar to those in a previous trial by the same investigators that obligated WBRT. Another multicenter study of this approach showed a 10-year OS of 35% with excellent neurocognitive function in patients who did not receive WBRT [127].

WBRT was completely eliminated from some studies of high-dose therapy for newly diagnosed PCNSL. In the larger study, 28 patients received induction with high-dose MTX and cytarabine followed by high-dose therapy with BEAM in chemosensitive patients. Fourteen patients underwent autologous HCT. With a median follow-up of 28 months, the median EFS was 5.6 months for all patients and 9.3 months for the 14 patients who underwent HCT. Six (43%) of these 14 patients were disease free at the time of the report [128]. In another study, by Alimohamed et al., 21 patients with PCNSL aged 34–69 years underwent autologous HCT with thioTEPA, busulfan, and cyclophosphamide conditioning after initial therapy with high-dose MTX and cytarabine. At a median follow up of 60 months, 11 patients (52%) remained alive and disease free without evidence of neurocognitive dysfunction [129]. Cheng et al. treated seven patients with high-dose MTX induction followed by high-dose therapy with thioTEPA, busulfan, and cyclophosphamide. Two patients in this study received autologous HCT as sole therapy for progressive disease after initial chemotherapy. Five of the seven patients remained disease free at 5–42 months from diagnosis, including the two patients with progressive disease after initial chemotherapy. These authors attributed their good results with these poor-prognosis patients to the use of agents such as thioTEPA and busulfan that have better CNS penetration than the BEAM regimen [130]. No neurotoxicity was observed in all of these studies during the follow-up period.

High-dose chemotherapy with autologous stem-cell support has also been tried as salvage therapy for patients with refractory or relapsed PCNSL or intraocular lymphoma after high-dose MTX. Soussain et al. reported a retrospective analysis of 79 such patients with a median age of 52.4 years who received autologous HCT after high-dose therapy with thioTEPA, busulfan, and cyclophosphamide. With a median follow-up of 56 months, the 5-year OS and EFS probability were 51 and 37.8%, respectively, in the whole population and 62 and 43.7%, respectively, among patients who were chemosensitive to salvage therapy [131]. A single case report described a patient with refractory PCNSL who underwent an allogeneic sibling HCT after non-myeloablative conditioning. This patient remained disease free 30 months after HCT, suggesting that a GVL effect may be operational in the CNS [132]. Results of autologous HCT for PCNSL have recently been reviewed by Reddy and Savani [133].

In summary, high-dose chemotherapy with autologous HCT is feasible as frontline therapy for chemosensitive PCNSL and carries a low treatment-related mortality, at least in patients less than 65 years of age. A reduced dose of WBRT can be given after autologous HCT with low short-term neurotoxicity, although it is not clear if high-dose chemotherapy can allow for complete elimination of WBRT. There is a suggestion that using agents such as thioTEPA and busulfan that have better CNS penetration for high-dose therapy is superior to conventional lymphoma regimens such as BEAM. Autologous HCT may have a role in salvaging patients who are refractory to initial chemotherapy or who have relapsed after chemoradiotherapy, although neurotoxicity appears to be high in this setting.

Blastic plasmacytoid dendritic cell neoplasm

Blastic plasmacytoid dendritic cell neoplasm (BPDCN) (formerly termed blastic NK-cell lymphoma, CD4$^+$/56$^+$ hematodermic neoplasm) is a malignancy of plasmacytoid dendritic cells with a marked predilection for skin involvement. Bone marrow involvement is common [1,134,135].

Given the lack of clarity of the lineage of BPDCN, patients have been treated with chemotherapy regimens for AML as well as acute lymphoblastic leukemia (ALL). Pagano et al. reported a series of 43 patients treated at 28 Italian centers [136]. The median OS was only 8.7 months, demonstrating the dismal treatment outcome for this disease. In this series, patients who were treated with ALL regimens had a significantly higher CR rate and OS than those treated with an AML regimen. Although there are some reports of durable CR after combination chemotherapy, the overall outcome with conventional combination chemotherapy alone is poor . Hence HCT has been attempted with hopes of achieving long-term survival. In the Italian series, six patients underwent allogeneic HCT. These patients had a significantly better OS than non transplanted patients (median OS 22.7 months vs. 7.1 months) [136]. Another case series of 47 patients were reported from France. Ten of these 47 patients underwent HCT (nine allogeneic, one autologous). The mean survival for the patients who underwent HCT was 31.3 months, which was significantly better than patients who did not undergo HCT [137]. Dietrich et al. performed RIC allogeneic HCT from unrelated donors in four patients ranging in age from 56 to 70 years. The two patients transplanted in CR were alive and disease free at 57 and 16 months whereas the two patients transplanted in active disease relapsed at 6 and 18 months after HCT [138]. Yoshimasu et al. reported a case of relapsed BPDCN that was successfully treated with unrelated cord blood allogeneic HCT [139]. Other single case reports of successful allogeneic HCT in children and adults have been published [140,141].

Based on the limited data available, allogeneic HCT offers the best chance for long-term survival if performed in CR1. Relapse rates are high in patients transplanted with active disease and NRM appears fairly high. There are single case reports of durable CR after autologous HCT in patients with widely disseminated disease including bone marrow involvement [142,143]. A report from Japan showed a 4 year OS and PFS of 82% and 73% respectively for 11 patients who underwent autologous HCT in CR1 [142]. Autologous HCT may be an option in selected patients to consolidate a first CR.

Other rare lymphoid malignancies

Hepatosplenic T-cell lymphoma is an aggressive T-cell lymphoma characterized by marked hepatosplenomegaly and almost invariable involvement of the bone marrow. Most cases are of the gamma/delta T-cell type [1]. Various reports have described durable remissions after allogeneic HCT for hepatosplenic T-cell lymphoma even in chemotherapy-refractory cases [144–147].

T-cell prolymphocytic leukemia (T-PLL) is an aggressive neoplasm with a poor response to chemotherapy [1,148]. A recent French registry analysis of 27 T-PLL cases (14 in CR) who had allogeneic HCT showed a 3 year OS and PFS of 36% and 26% respectively. A high NRM (31%) was observed [149]. Kruspe et al. reviewed the literature on allogeneic HCT for T-PLL. Among 13 published case reports, including a case of their own, there were 10 patients who remained in CR for periods ranging from of 2 to 48 months after HCT. Notably, only four of these 13 were in CR at the time of HCT [150].

Subcutaneous panniculitic T-cell lymphoma mostly affects young adults who present with subcutaneous nodules. A hemophagocytic syndrome may occur [1]. In a review of 21 patients treated with a variety of modalities, including five patients who received HCT, the overall survival from diagnosis was only 15 months [151]. There are single case reports of prolonged survival after autologous HCT even in patients who have relapsed disease and other adverse prognostic factors such as elevated lactate dehydrogenase and bone marrow involvement [152–156]. Allogeneic sibling HCT has been reported in a patient with progressive disease who remained in CR 31 months after allogeneic HCT [157].

HCT should be considered early in the treatment plan for the three extremely rare neoplasms discussed in this section. For hepatosplenic lymphoma and T-prolymphocytic leukemia, allogeneic HCT upfront appears to be the treatment of choice, preferably after inducing remission with chemotherapy or antibody-based therapy. There is currently no evidence to suggest a benefit for autologous HCT for these two disorders. In the case of panniculitic T-cell lymphoma, it appears reasonable to perform autologous HCT to consolidate an initial CR or at chemosensitive relapse. Allogeneic HCT could be reserved for primary refractory disease or relapsed cases that are chemorefractory and for patients who have poor prognostic factors such as extensive bone marrow involvement. Although no conclusions about the overall effectiveness of HCT can be drawn from the reported cases, at present HCT is the only therapy known to produce durable remissions in these aggressive lymphoid malignancies.

CHAPTER 68

Adoptive T-cell Therapy for Viral Disease in the Setting of Hematopoietic Cell Transplantation

Catherine M. Bollard[1] **and Helen E. Heslop**[2]

[1] The George Washington University, School of Medicine and Health Sciences, Children's National Health System, Washington, DC, USA
[2] Baylor College of Medicine, Houston Methodist Hospital and Texas Children's Hospital, Houston, TX, USA

Introduction

Following hematopoietic stem cell transplantation (HSCT), reconstitution of the recipient immune system occurs with donor-derived cells. Murine and human studies have clearly shown that the presence of a virus-specific T-cell immune response is required to control viral infections [1–3] and viral reactivation or infection is therefore an important cause of morbidity and mortality until this process is complete. A number of factors influence the risk of viral infections, including the degree of tissue mismatch between donor and recipient, the degree of immunosuppression, and the immune status of the donor. For example, the use of antithymocyte globulin (ATG) or alemtuzumab in conditioning regimens has been associated with a significant increase in the incidence of viral infections [4]. As absence of a virus-specific cellular immune response is clearly associated with viral reactivation and disease in these patients [3,5,6], cellular immunotherapy with virus antigen-specific T cells [cytotoxic T-lymphocytes (CTLs)] to restore viral-specific immunity is an attractive option. The first study that evaluated adoptive transfer of virus-specific T cells was published in 1992 [7], and since then this strategy has been tested for a number of viruses, with many studies showing encouraging response rates. Recent manufacturing advances have greatly simplified production so that several approaches are now being evaluated in late phase or licensing studies that may allow adoptive transfer of virus-specific CTLs to become standard of care post-HSCT.

Common viral infections post-transplant

The number of viruses associated with disease after HSCT is increasing owing to increased surveillance with more reagents becoming available for detection by polymerase chain reaction (PCR) and the discovery of new viruses [8]. Some new viruses such as metapneumovirus are clearly associated with disease whereas the contribution of other viruses to post-transplant morbidity is less clear. Transplant recipients are at risk of both reactivation of latent viruses such as cytomegalovirus (CMV), BK virus, herpes simplex virus (HSV), varicella zoster virus (VZV), human herpesvirus 6 (HHV6) and Epstein–Barr virus (EBV) and new infections with respiratory viruses such as adenovirus, parainfluenza, and influenza. Antiviral pharmacologic agents are available for some of these viruses but their use is limited by significant toxicities and the outgrowth of drug-resistant mutants. Moreover, infections often recur when the agents are discontinued.

Cytomegalovirus

CMV is a latent beta-herpesvirus that usually causes an asymptomatic infection in immunocompetent individuals. Around 65% of healthy adults are seropositive and in these individuals CMV can replicate in epithelial cells, fibroblasts, and monocytes. CMV-specific $CD4^+$ and $CD8^+$ lymphocytes play an important role in immune protection from both primary infection and subsequent reactivations, so seropositive individuals or seronegative recipients of seropositive grafts have a significant risk of reactivation and infection post-transplant [9].

Epstein–Barr virus

EBV is a gamma-herpesvirus that infects more than 95% of the world's population. Primary infection usually produces a mild self-limiting disease, which is followed by latent infection in B cells and productive replication in B cells and mucosal epithelium. In immunocompromised hosts, outgrowth of B cells expressing Type 3 latency may lead to the development of post-transplant lymphoproliferative disorder (PTLD) [10]. The overall incidence of PTLD after HSCT is less than 1%, but the incidence is increased in recipients with an underlying diagnosis of immunodeficiency and for recipients of stem cells from unrelated or human leukocyte antigen (HLA)-mismatched donors who receive grafts that are selectively depleted of T cells to prevent graft-versus-host disease (GVHD). PTLD is highly susceptible to control by virus-specific T cells [11].

Adenovirus

Adenovirus is a non-enveloped lytic DNA virus. Humans are susceptible to infection with 51 serotypes forming six distinct adenovirus species (A–F), which differ in their tissue specificity and virulence. Although acute infection is rarely fatal in healthy adults, it is a significant cause of morbidity and mortality in immunocompromised individuals, in whom it may produce pneumonia, hemorrhagic cystitis, nephritis, colitis, hepatitis, and encephalitis. Transplant recipients may develop new infections but may also reactivate previous infections with this virus. Adenovirus has a particularly high incidence after pediatric HSCT. Several reports have shown that clearance of adenovirus infection is associated with detection of adenovirus-specific T cells [6,12] and recovery is significantly delayed in recipients of matched unrelated donor and haploidentical transplants who receive intensive immunosuppression such as with alemtuzumab [13].

Varicella zoster

VZV, a member of the herpesvirus family, causes chickenpox with a primary infection and shingles upon viral reactivation. Once the primary infection has resolved, the virus becomes latent in the dorsal root ganglia. Reactivation of VZV can occur in approximately 30% of patients after HSCT and correlates with the degree of immunosuppression [8].

BK virus

Human polyomavirus type I, commonly called BK virus (BKV), infects up to 90% of humans worldwide before the age of 10 years. Shedding of BK in the urine is frequently seen in transplant recipients as in healthy individuals and some of these recipients will develop BKV-associated hemorrhagic cystitis [8].

HHV6

Most individuals are infected with HHV6 in childhood and the virus remains latent in lymphocytes and monocytes [14]. HHV6 reactivation is common during the early period after allogeneic HSCT transplant, with viremia occurring in approximately 40–60% of patients, and some patients develop symptomatic disease such as encephalitis. Recovery of interferon-gamma (IFN-γ)-producing HHV6-specific T-cells may be associated with ability to control the reactivation [15].

Herpes simplex virus

HSV is a double-stranded, enveloped DNA virus that becomes latent in sensory ganglia after primary infection. Reactivation in the peri- and post-transplant setting is decreased by prophylaxis with acyclovir but it can still be associated with significant morbidity [8].

Respiratory viruses

HSCT patients are susceptible to community-acquired and nosocomial spread of respiratory viruses such as respiratory syncytial virus (RSV), influenza, and parainfluenza [8]. These infections can have a high mortality when they develop in the early post-transplant period and would be amenable to immunotherapy approaches.

Prerequisites for T-cell therapy

Since recovery of virus-specific T cells is clearly associated with protection from viral infection [16], adoptive immunotherapy to decrease the time to immune reconstitution or to treat viral reactivations and infections is an attractive approach. Donors who are seropositive for a particular virus will have circulating T cells specific for this virus, with the frequency ranging from very low levels to up to 1% of total T cells for the latent herpes viruses CMV and EBV. If the donor has a high frequency of virus-specific T cells, they may be directly selected from an apheresis product, although this option is generally only viable for viruses where the frequency of virus-specific precursors is high. In all cases, however, virus-specific T cells can be generated in vitro from seropositive donors by repeated stimulation with antigen-presenting cells (APCs) that express viral antigens. Under these conditions, alloreactive T cells should not survive.

Choice of antigen

To generate virus-specific T cells *ex vivo* requires a defined immunogenic antigen and an antigen-presenting cell that can effectively present the antigen to T cells with appropriate costimulatory signals. It is therefore necessary to know, for a given virus, which viral antigens are immunodominant and induce protective T cells. Also, it is crucial to identify the antigens that are most important for viral persistence and will therefore be the best targets for immunotherapy. For some viruses such as CMV and EBV, the immunodominant antigens expressed at different stages of infection have been well defined [5], but for other viruses such as adenovirus the appropriate target antigens had to be identified to design adoptive immunotherapy studies [17]. Antigen characterization has been simplified by the availability of bioinformatic tools that allow the effective mapping of viral epitopes recognized by both CD4$^+$ and CD8$^+$ T cells.

Antigen presentation

The defined immunogenic antigens must be presented on an autologous APC that expresses major histocompatibility complex (MHC) antigens to present virus antigen-derived peptides in addition to costimulatory molecules sufficient to induce T-cell activation and expansion. The choice of APC also depends on the type of antigen to be used and the proposed method of delivery. Some approaches use whole virions as antigen whereas others use specific viral genes, proteins, or peptides and the APCs used include fibroblasts, dendritic cells (DCs), monocytes, and B cells. Specific examples include the following:

1. *Whole virus or viral lysate to expand virus-specific T cells.* The use of the entire viral antigen (e.g., CMV) enables a broad CTL response to be generated and CMV lysate or antigen has been used to infect fibroblasts or pulse DCs [18,19]. Similarly, intial studies used EBV-infected lymphoblastoid cell lines (LCLs) to reactivate EBV-specific CTLs, which produced a broad EBV-specific response [20]. However, the use of CMV lysate containing infectious CMV- or EBV-transformed LCLs makes it difficult to develop the approach for late-phase trials.
2. *Whole proteins*, such as the EBNA-1 to expand EBNA-1-specific T cells for EBV-associated PTLD [21].
3. *Gene-modified APCs.* An adenoviral vector encoding CMV pp65 has been used to genetically modify various APCs including DCs, monocytes, and LCLs to expand T cells specific for CMV pp65 [22,23]. This approach has the added advantage of also enabling the expansion of T cells recognizing the adenoviral virion proteins hexon and penton expressed by the adenoviral vector. In studies in which the adenoviral vector is used to tranduce LCLs, the responding T cells are also exposed to latent and early lytic cycle EBV proteins expressed by the LCLs [22,24]. More recently, to avoid the use of viral vectors, plasmids expressing viral antigens derived from CMV, EBV, and adenovirus have been used to transfect DCs to stimulate multi-virus-specific T cells [25].
4. *Peptides and peptide mixtures.* Several groups have explored the use of peptides such as the A2-restricted CMV pp65 epitope NLV to stimulate virus-specific T cells [26]. Concerns with this approach are that targeting a single epitope will result in escape mutants and also that it is restricted to specific HLA types. Recently, the availability of overlapping peptide pools or pepmixes where overlapping peptide libraries represent the entire protein sequences of the target viral antigens has provided a convenient source of antigen that has been validated in preclinical studies [27–30] and is being tested in several clinical trials.

Expansion strategies

"Classic" ex vivo expansion

In the "classic" expansion approach, APCs expressing the relevant antigens are generated and then used in multiple stimulations (usually weekly) to activate and expand a virus-specific T-cell product which is enriched for the T cells targeting the viral antigens expressed by the APC (Figure 68.1a). The advantage of this strategy is that the prolonged ex vivo culture enriches for virus-specific cells

Figure 68.1 GMP compliant approaches for the generation of CMV-specific T cells. (a) "Classic" ex vivo expansion method of CMV-CTL manufacture where antigen-presenting cells (APCs) are prepared using either dendritic cells or monocytes or EBV-transformed B lymphoblastoid cell lines (LCLs). The APCs are then either pulsed with CMV peptides or protein or infected with CMV lysate or transduced with an adenoviral vector expressing the CMV pp65 transgene. The APCs are then irradiated and used to stimulate peripheral blood mononuclear cells (PBMCs) from the same donor. Approximately 9–12 days later, and weekly thereafter, the T cells are restimulated with the APCs usually in the presence of IL-2. At the end of the CTL manufacturing process (approximately 4 weeks), the CTLs are frozen and released. Functional testing is performed prior to infusion into the patient. (b) This shows how CMV-specific T cells can be selected using multimer selection. In the example shown, T cells recognizing the HLA A2-restricted CMV pp65 epitope NLV are selected directly from the donor PBMCs by first incubating with the HLA–peptide tetramer and then selecting the tetramer-positive T cells with magnetic beads. This process generally takes less then 1 day of processing. (c) This shows an alternative method of rapidly generating a CMV-specific T cell line using the gamma capture technology. Donor PBMCs are stimulated with either recombinant CMV protein or CMV lysate or GMP grade-selected HLA-restricted CMV peptides or overlapping peptides spanning entire CMV antigens such as pp65. After overnight stimulation, IFN-γ-secreting cells are selected using a Cytokine Secretion System and a CliniMACS immunomagnetic separation device (both from Miltenyi Biotech) which "capture" the IFN-γ-secreting CMV-specific T cells. CMV-specific T cells selected using this methodology can either be infused immediately after the isolation procedure or cryopreserved for future use. The manufacturing time for this procedure is 1–2 days. (For a color version of this figure, please see the color plate section.)

while depleting alloreactive T cells. Moreover, under most culture conditions, the resulting product is broadly specific, containing both CD8$^+$ and CD4$^+$ T cells, which is considered advantageous since the presence of antigen-specific CD4-helper T cells is important for survival of cytotoxic CD8-positive T cells in vivo. The disadvantage is the long time required for manufacture. For example, EBV-specific T cells generated using LCLs as APCs require approximately 6 weeks for the manufacture of the LCLs generated by infecting donor peripheral blood mononuclear cells (PBMCs) with a laboratory strain of EBV, then 4–6 weeks to stimulate and expand EBV-specific CTLs by co-culture with irradiated LCLs.

Rapid CTL selection or expansion

In an attempt to make CTL manufacture simpler and more broadly applicable, several groups have developed methods for rapid virus-specific T-cell generation. All of these more rapid manufacturing approaches rely on the ability of small numbers of antigen-specific T cells to undergo substantial expansion in vivo as soon as they encounter antigen, thus providing protection against the virus being targeted. A potential caveat is that if the virus being targeted is not latent (e.g., adenovirus), the T cells may not be effective in the prophylaxis setting when antigen may not be present in vivo at the time of adoptive T-cell transfer. Moreover, the potential for GVHD may be increased since the shorter culture period may result in an increased chance for residual alloreactive T-cell populations to be present in the product. Rapid approaches that have been used clinically are highlighted below [31–35].

Multimer selection

One potential strategy for viruses such as CMV where seropositive donors may have a high frequency of virus-reactive T cells is to select directly T cells reactive with an immunogenic peptide using magnetically labeled peptide multimers (Figure 68.1b). The first report of this approach used incubation with HLA–peptide tetramers containing peptides from CMV pp65 or IE-1 followed by selection with magnetic beads to isolate CMV peptide-specific CD8$^+$ T cells from the donor's peripheral blood [35]. Although the investigators infused very small numbers of T cells, CMV-specific activity could be detected in the recipient's blood within 10 days. More recently, Schmitt et al. used a streptamer (a multimer conjugated to a marker that allows isolation and can then be dissociated) technique to select CMV-specific T cells from the transplant donors. They transferred CMV-specific CD8$^+$ effector T cells to HSCT recipient patients with recurrent CMV reactivations and saw reconstitution of CMV immunity and clearance of elevated CMV viral load [33]. These results are encouraging and multimer selection is being tested in a phase III randomized trial in the United Kingdom to treat CMV reactivation (NCT01077908). However, caveats include the large volume of donor blood required for manufacturing, the limitation that donors need to express HLA alleles for which viral peptides are available and the requirement that sufficient circulating T cells specific for the peptide must be detected in the donor. There is also a risk of viral evasion since the administered cells have restricted specificity [36].

IFN-γ capture

Another approach for rapid selection of virus-reactive T cells is the IFN-γ capture technology that involves selecting T cells that respond to a *single* stimulation by APCs expressing viral antigens (Figure 68.1c). In this approach, only the T cells secreting IFN-γ in response to the viral stimulus are selected. This strategy has been used for the selection of CMV-, EBV-, and adenovirus-specific T-cell populations (Table 68.1). Advantages of this strategy include the rapid manufacturing process, which permits the urgent treatment of a sick patient with viral infection/disease. Further, the approach is not restricted to certain HLA types and will select polyclonal T cells recognizing multiple epitopes, which reduces the risk for immune evasion. However, the limitations are again the large volumes of donor blood required for the T-cell manufacture and also the potential for the selection of alloreactive IFN-γ-secreting T cells.

Single stimulation and expansion with APCs pulsed with peptides or transfected with plasmid-derived viral antigens

Several groups are exploring approaches that avoid the need for apheresis by using a single stimulation of donor PBMCs using APCs pulsed with peptides or plasmids followed by a short ex vivo culture of 7–14 days in optimized cytokines to expand virus-specific T cells. The advantages of such strategies are that they not only use a small volume blood draw but also avoid the use of live viruses in APCs. Dendritic cells nucleofected with DNA plasmids encoding immunogenic EBV (LMP2, EBNA1, BZLF1), adenovirus (hexon, penton), and cytomegalovirus (pp65 and IE1) have been used as APCs to generate multivirus CTL lines after expansion with the cytokines IL-4 and IL-7 [25]. The use of overlapping peptide pools as a source of antigen to expand T cells from PBMCs is being increasingly evaluated since it further simplifies the process and shortens the culture time [27,29,30]. Clinical trials using these approaches are under way [37].

Clinical results using immunotherapy targeting single viruses

The majority of T-cell studies have focused on CMV, EBV, and adenovirus, and trials of donor-derived CTLs specific for single viruses are summarized in Table 68.1. Although methodologies are being developed for other viral pathogens such as BK virus [27,29], HHV-6 [38], and VZV [28], clinical trial results have not yet been reported.

EBV

T-cell therapies aimed at reconstituting EBV-specific T-cell immunity have been used for around 20 years [20,39–41]. In the first reported studies, unmanipulated donor lymphocyte infusions (DLIs) were administered to HSCT recipients with established disease [42,43]. The approach was effective since most EBV-seropositive individuals have a high frequency of EBV-specific T-cell precursors and the infusion of unmanipulated donor lymphocytes resulted in restoration of the EBV-specific immunity and resolution of EBV–PTLD in many cases [42–44]. The Sloan Kettering group recently reported a long-term response rate of more than 70% of HSCT patients with established PTLD [45]. However this approach is limited by the presence of alloreactive T cells in the DLI product and the resultant potential for GVHD [43–45].

To overcome this problem of alloreactivity, EBV-specific T cells generated using repeated stimulations with LCLs as APCs were manufactured for high-risk recipients receiving T-cell-depleted transplants from mismatched or unrelated donors. We published results for 114 patients who received EBV-specific CTLs as prophylaxis ($n = 101$) or treatment ($n = 3$) for PTLD [39]. The approach had relatively limited toxicity with no development of de novo GVHD after EBV-specific T-cell therapy, and the main adverse

Table 68.1 Clinical trials using transplant donor-derived single virus-specific CTLs for prophylaxis or treatment of viral infections

Virus	No. of patients	Transplant patient population	Type of CTL	Acute GVHD	Antiviral effects	Ref.
EBV	113	*Prophylaxis:* T-depleted HSCT from unrelated or mismatched family donor or diagnoses with high risk *Therapy*: patients with PTLD	LCL-activated	8 had a recurrence of previous acute GVHD post-CTLs	*Prophylaxis:* None of 101 developed PTLD *Treatment:* Induced CR in 11/13 patients	Rooney et al. 1995 [20] Heslop et al. 1996 [41] Rooney et al. 1998 [40] Heslop et al. 2010 [39]
EBV	14	HSCT recipients with biopsy proven PTLD	LCL-activated	None	CRs in 10 patients 4 with progressive disease	Doubrovina et al. 2012 [45]
EBV	6	Recipients of T-depleted HSCT or of ATG/OKT3 conditioning with elevated EBV viral load	LCL-activated	None reported	Decreased EBV DNA levels in 5 patients; 1 patient died of PTLD	Gustafsson et al. 2000 [69]
EBV	1	T-depleted HSCT recipient with PTLD	LCL-activated	1 patient reactivated acute skin GVHD	Patient attained CR	Lucas et al. 1998 [44]
EBV	1	Mismatched HSCT recipient with PTLD	LCL-activated	None	Patient failed to respond	Imashuku et al. 1998 [70]
EBV	4	Haploidentical HSCT recipients – 3 with recurrent PTLD post rituximab and 1 with elevated viral load	LCL-activated	None	CRs in 3 patients with recurrent PTLD post-rituximab; decrease in EBV DNA in patient without overt PTLD	Comoli et al. 2007 [46]
EBV	6	HSCT (5 haploidentical) recipients with biopsy-proven PTLD not responding to standard therapy		None	CRs in 3 patients; no response in 3 others	Moosmann et al. 2010 [48]
EBV	10	HSCT recipients with refractory EBV viremia and/or PTLD	Cells responding to EBV nuclear antigen 1 (EBNA-1) protein or overlapping peptides using IFN-γ capture	1 transient skin GVHD	CR in 7/10 patients	Icheva et al. 2013 [21]
CMV	14	Matched sibling HSCT recipients at risk of CMV reactivation	$CD8^+$ CMV-specific T-cell clones, stimulated by autologous fibroblasts infected with the AD169 strain of CMV	3 patients developed grade I or II GVHD post-infusion	Reconstitution of CMV-specific immunity in all patients. No patients developed CMV viremia or CMV disease	Riddell et al. 1992 [7] Walter et al. 1995 [18]
CMV	8	HSCT recipients with persistence or recurrence of CMV DNA in the peripheral blood after 4 weeks of antiviral chemotherapy	CMV-specific CTL lines, generated using CMV lysate and antigen	None	5 cleared after 1 dose of CTL; 1 pt cleared after a second dose; 1 did not clear, 1 not evaluable	Einsele et al. 2002 [50]
CMV	16	HSCT patients with CMV reactivation	CMV-specific CTLs generated using dendritic cells pulsed with CMV antigens derived from a CMV-infected human lung fibroblast cell line	3 developed grade I skin GVHD that responded to topical steroids in all cases	Reconstitution of immunity to CMV. In 8 cases antiviral drugs were not required. Subsequent reactivation occurred in only two patients	Peggs et al. 2003 [19]
CMV	25	Haploidentical HSCT recipients at risk of CMV reactivation	CD4 clones of CMV-specific T cells derived by stimulation with CMV antigen	1 case	7 patients underwent CMV reactivation and 5 developed CMV disease, which was fatal in 2	Perruccio et al. 2005 [49]
CMV	9	Patients expressing HLA-A*0101, *0201, HLA-B*0702, *0801, or *3502 with CMV reactivation	CMV-specific CD8 T cells staining with HLA–peptide tetramers and selected with magnetic beads	1 grade I 1 grade II	8/9 patients cleared CMV viremia	Cobbold et al. 2005 [35]
CMV	9	Allogeneic HSCT recipients at risk of CMV reactivation	CTLs stimulated with dendritic cells pulsed with the $CD8^+$ HLA-A2 restricted epitope NLVPMVATV derived from pp65	3 developed grade III GVHD, which was fatal in one	Increase in NLV-tetramer binding T cells in 6 recipients. 2 patients developed reactivation which cleared without therapy. No patients developed CMV disease	Micklethwaite et al. 2007 [26]
CMV	30	Allogeneic HSCT recipients at risk of CMV reactivation	CMV-specific CTLs generated using DCs pulsed with CMV lysate	None in 19 Grade I in 7 Grade II in 1 Grade III in 3	Reconstitution of CMV immunity and prevention of late reactivations	Peggs et al. 2009 [71]
CMV	16	Allogeneic HSCT recipients with CMV disease or viremia refractory to antiviral chemotherapy	Ex vivo stimulation with pp65 protein, followed by isolation of IFN-γ-producing cells	1 possible (GI bleeding)	Partial or complete response in 14/16 patients	Feuchtinger et al. 2010 [51]

CMV	18	Allogeneic HSCT recipients at risk of or with early CMV reactivation	CMV-specific T cells, directly isolated on the basis of IFN-γ secretion in response to recombinant pp65 or pool of overlapping peptides from CMV pp65	7 with GVHD (5 grade I skin only)	Reconstitution of CMV immunity *Prophylaxis:* None of the 7 patients required antiviral drug therapy in the next 6 months *Preemptive:* 2 of 11 patients required no antiviral drugs and 9 required antiviral therapy to clear viral load while CMV immunity recovered	Peggs et al. 2011 [31]
CMV	2	HSCT recipients with recurrent high CMV antigenemia	Selection of CMV pp65-specific T cells with streptamer technology	None	2/2 with viral clearance	Schmitt et al. 2011 [33]
CMV	7	HSCT recipients with CMV reactivation for >2 weeks	Stimulation with peptide mixes derived from full-length pp65 and IE1	None	5 /7 had increase in CMV activity in peripheral blood with CR or PR of viral load	Bao et al. 2012 [72]
CMV	6	Allogeneic HSCT recipients with persisting CMV viremia for >2 weeks while receiving pharmacotherapy or early relapse (within 2 weeks) after therapy	Stimulation with HLA-A*0201-restricted and/or HLA-B*0702-restricted CMV pp65 peptides (NLV/TPR), selection by IFN-γ capture, then expanded for 7–14 days	None	6/6 cleared CMV viremia	Meij et al. 2012 [52]
CMV	13	Allogeneic recipients with persistent CMV viremia, refractory to at least 2 weeks of ganciclovir or foscarnet	T-cells were stimulated by autologous monocyte-derived DCs loaded overlapping peptides from CMV pp65. The culture period was 21–35 days	None	12/13 cleared viremia by 2–8 weeks post-infusion; one failed to respond	Koehne et al. 2012 [37]
ADV	9	HSCT recipients with persistent ADV after 2 weeks of therapy	IFN-γ capture after short in vitro stimulation with ADV antigen	1 grade II GVHD skin	Adoptive transfer of ADV-specific immunity was successful in 5/6 evaluable patients and 4 cleared adenovirus infection	Feuchtinger et al. 2006 [54]
JCV	1	Matched sibling recipient with JCV-associated PML	Stimulation with peptides derived from VP1 and large T viral proteins	None	JCV-DNA was cleared in the cerebrospinal fluid	Balduzzi et al. 2011 [55]

effect was reversible inflammatory reactions at disease sites in four patients with PTLD [39]. Of the patients who received the CTLs as prophylaxis, up to a 4-log expansion of EBV-specific T cells was observed in vivo and none developed PTLD compared with an 11.5% incidence in controls. Thirteen patients received EBV-specific CTLs for active disease and 11 achieved durable remissions. One of the non-responders developed an escape mutant which deleted immunodominant epitopes in the patient's tumor [36]. Important information regarding the persistence of the infused CTLs was also obtained from this study since the first 26 patients received T cells that had been genetically modified with a retroviral vector encoding the neomycin resistance gene. Tracking of this marker gene using quantitative PCR confirmed that the infused T cells persisted for up to 9 years [39].

In another study, Doubrovina et al. treated 14 patients with active PTLD with donor-derived EBV-specific T cells and showed complete responses in 10 [45]. In three of the non-responders, the CTLs recognized the EBV–LCLs transformed with the B-95 laboratory strain of EBV used to generate them, but did not recognize the tumor cells or spontaneous LCLs outgrowing from the patients' blood. This result illustrates that antigenic differences between EBV strains causing PTLD and the laboratory B95-8 strain used to generate LCLs for manufacturing is a potential problem. In the fourth patient, the donor was only a 7/10 match with the recipient and the donor CTL line was skewed in its response to EBV antigens by the HLA antigen A1101, which was present only in the donor [45]. This observation along with the immune escape observed by our group [36] confirms the hazards of infusing T cells with a restricted specificity.

The results of these and other studies (Table 68.1) confirmed that donor-derived EBV-specific CTL therapy is safe and effective when used either as prophylaxis or as treatment for PTLD after HSCT. However, although the manufacturing methodology is reproducible, and can be exported to other institutions, a limitation is the 2–3-month time frame for the generation of EBV-specific CTLs (Figure 68.1a). Although many of these studies using EBV-specific T cells were conducted during the pre-rituximab era, there are still an appreciable number of patients who have rituximab-resistant disease that is responsive to EBV-specific T cells [46]. Hence other, more rapid, manufacturing strategies have been evaluated for this disease. Multimer selection (Figure 68.1b) has been used to treat EBV PTLD in a recipient who developed PTLD after a cord blood transplant. In this case, HLA A2-restricted T cells specific for epitopes in two EBV antigens were selected from a haploidentical donor, infused, and expanded greatly, inducing a clinical response [47]. EBV PTLD recurred at 12 months after transplantation and a second infusion also induced a response.

Other groups have evaluated the IFN-γ capture technology to select donor-derived EBV-specific T cells to treat patients with PTLD after HSCT. Moosmann et al. incubated donor mononuclear cells with 23 class I and II peptides derived from 11 EBV antigens and selected the T cells that secreted IFN-γ in response to these peptides [48]. Three patients treated early in their disease course responded to the T-cell therapy, but three patients with more advanced disease failed to respond [48]. Icheva et al. used APC pulsed either with whole EBNA-1 protein or with EBNA-1 overlapping peptide pools to stimulate EBNA1-specific T cells, which were then selected by IFN-γ capture (Figure 68.1c). The selected EBNA1-specific T cells were effective in seven out of 10 patients treated for PTLD [21]. Moreover, in both of these studies, no significant toxicities were seen and only one patient developed grade I GVHD of the skin, which was transient [21]. These results are certainly encouraging, although it is still unclear whether there is increased incidence of failure due to immune escape when only targeting a limited number of EBV antigens and/or epitopes. Further, it is currently unclear which EBV antigens will most likely induce T cells that will be protective in vivo.

CMV

The administration of CMV-specific T cells after HSCT was first explored by the groups of Riddell and Walter [7,18], who infused donor-derived CMV-specific $CD8^+$ clones in a dose-escalation study to recipients of matched sibling donor grafts. CMV-specific $CD8^+$ T-cell responses were detected in the blood of all patients following infusion and no adverse events were reported [7,18]. No patient in this study developed CMV disease, thereby demonstrating the importance of CMV-specific $CD8^+$ T cells in preventing CMV reactivation after HSCT [18]. An interesting observation in this study was that the magnitude of the CMV-specific T-cell responses declined in patients who lacked detectable $CD4^+$ CMV-specific T cells in vivo, implying that as in several animal models, $CD4^+$ T cells are required for long-term persistence of adoptively transferred $CD8^+$ T cell clones. This study was an important proof of principle demonstrating the potential of adoptive immunotherapy to reconstitute antiviral immunity, but the use of donor fibroblasts as APCs and the AD169 strain of CMV, and also the prolonged manufacturing process for clones, precluded broader application.

Numerous groups have built on these initial studies of CMV-specific T-cell therapy for patients after HSCT. Peggs et al. used DCs pulsed with CMV antigen derived from a CMV-infected human lung fibroblast cell line to stimulate and expand polyclonal CMV-specific $CD4^+$ and $CD8^+$ T cells [19]. The use of the entire CMV antigen permitted the expansion of a CTL product with broad specificity. Patients were infused at the time of first PCR reactivity. There were no infusion-related toxicities and none of the 16 patients developed CMV disease, although two patients did develop CMV reactivation and were successfully treated with ganciclovir [19]. In this study, only three patients developed grade I skin GVHD, and all three responded to topical steroids. It is important to note, however, that these patients had early withdrawal of their GVHD prophylaxis around the time of T-cell infusion.

Perruccio et al. administered $CD4^+$ CMV-specific T-cell clones rather than polyclonal CTLs to 25 recipients of haploidentical donor grafts [49]. Since clearance of CMV is mediated by $CD8^+$ T cells, it was thought that the infused $CD4^+$ cells might have provided T-cell help to stimulate and expand endogenous CMV-specific $CD8^+$ T cells. T-cell clones were expanded after infecting donor PBMCs with CMV antigens and infused as a single infusion at a dose range of 10^5–10^6 cells/kg. Infusion of CMV-specific $CD4^+$ clones was effective in preventing CMV reactivation in 16 patients. However, seven patients reactivated CMV and five developed CMV disease, two of whom died, suggesting that the use of a broad product containing both $CD4^+$ and $CD8^+$ T cells may produce greater therapeutic benefit.

Based on the successful application of CMV-specific T cells as prophylaxis, Einsele et al. investigated the therapeutic utility of adoptively transferring CMV-specific CTLs to patients who had persisting or relapsing CMV infection despite antiviral pharmacotherapy [50]. CMV-specific T cells were initiated by pulsing donor-derived PBMCs with CMV lysate and expanded using autologous irradiated feeder cells and CMV lysate in the presence of interleukin-2 (IL-2). Eight patients received CMV-specific T cells at a dose of 1×10^7 cells/m^2 and there were no adverse events [50]. Of the seven evaluable patients, six cleared viremia long term after one or two doses of T cells coincident with an increase in both CD4$^+$ and CD8$^+$ CMV-specific T cells [50]. The advantage of this approach is that it relies on the monocytes infected with the CMV lysate for antigen presentation and thereby avoids the use of DCs. However, there still remains the potential risk for infection when using CMV lysate.

In an attempt to move away from the use of live CMV virus or viral antigens, several groups have explored approaches using CMV protein or peptides to expand T cells [26,30]. Initially immunodominant peptides restricted by common HLA alleles were used, although the recent availability of overlapping peptides has obviated the problem with HLA restriction. Several strategies have been used, including two studies in which DCs pulsed with single peptides or peptide mixes were used to expand CMV-specific T cells [26,27], and three groups used IFN-γ capture to select the T cells responding to the relevant peptides [31,51,52]. Feuchtinger et al. infused CMV-specific T cells isolated by IFN-γ capture after stimulation with pp65 protein into 18 patients after allogeneic HSCT with CMV disease or viremia and reported responses in 83% [51]. Peggs et al. [31] infused cytomegalovirus-specific T cells, isolated from donor apheresis after stimulation with recombinant CMV pp65 protein or overlapping peptides derived from the CMV pp65 antigen, to 25 recipients of related-donor HSCT and reported reconstitution of CMV immunity. Meij et al. infused T cells stimulated with two immunodominant CMV pp65 peptides (NLV which is HLA-A*0201-restricted and TPR which is HLA-B*0702-restricted) to six recipients with CMV reactivation who all achieved complete responses [52].

The use of HLA tetramers avoids the use of an APC to select donor-derived CMV-specific CD8$^+$ T cells [35]. In a study evaluating this approach for CMV, nine patients received a median dose of 8.6×10^3 CMV tetramer-staining CTLs/kg. CMV-specific CTLs were detectable at increasing levels in the peripheral blood within 10 days of infusion and 8/9 patients cleared the viremia, including one patient with drug-resistant disease [35]. More recently, Schmitt et al. used the streptamer technique and treated two patients with pp65-specific T cells, showing viral clearance in both [33]. This is therefore a promising approach but again is limited to small numbers of donors who have sufficient circulating T cells reactive with a known HLA-restricted CMV peptide epitope.

Overall, the response rates in studies of donor-derived CMV-specific CTLs to treat CMV reactivation or disease have been encouraging, ranging from 80 to 100%. In addition, when used in the prophylaxis setting, apart from the five patients who received CD4$^+$ clones, no other patients were reported to develop CMV disease (Table 68.1).

Adenovirus

There are published reports on the use of T cells solely targeting adenovirus, although a case report documented the successful use of DLI in a patient with hemorrhagic cystitis due to adenovirus infection [53]. More recently, Feuchtinger et al. reported a study that selected adenovirus-reactive T cells by simulation of donor PBMCs with adenoviral antigen followed by IFN-γ capture [54]. Nine pediatric patients with systemic adenoviral infection after HSCT received the resulting product in doses ranging from 1.2×10^3 to 50×10^3 T cells/kg. Although the infused cell number was very low, four of the nine patients cleared the virus [54].

JC virus

The polyomavirus JC (JCV) is associated with the usually fatal disease progressive multifocal leukoencephalopathy (PML). Balduzzi et al. generated JCV-specific T cells by stimulation of donor PBMCs with overlapping 15-mer peptides derived from the VP1 and large T viral antigens and administered these cells to a patient diagnosed with JCV-associated PML after HSCT [55]. After T-cell infusion, JCV-specific T-cells were detected in the peripheral blood coinciding with clearance of JCV–DNA in the cerebrospinal fluid and a dramatic clinical improvement. No adverse events attributable to CTL infusion were reported. Although this is a single case, it supports the use of JCV-specific T-cell immunotherapy to restore T-cell immunity to this virus and control disease in patients after HSCT.

Clinical results using immunotherapies targeting multiple viruses

Since it is not infrequent for patients after HSCT to develop multiple viral infections, several groups have explored the use of T cells targeting more than one virus to administer to patients after HSCT either as treatment or prophylaxis. These trials are summarized in Table 68.2.

Targeting CMV, EBV, and adenovirus

In the first reported study using multivirus-specific T cells, the group at Baylor College of Medicine developed a strategy to generate trivirus-specific donor-derived T-cell lines recognizing CMV, EBV, and adenovirus [22]. A chimeric adenovirus-CMV pp65 vector (Ad5f35-pp65) was used to modify monocytes and EBV LCLs that served as APCs to generate a single culture of CTLs specific for EBV, CMV, and adenovirus. A total of 26 patients received the trivirus-specific CTL products either as prophylaxis or as treatment in doses ranging from 1×10^7 to 1×10^8 cells/m^2. None developed more than grade II GVHD or other toxicities over the 3 months of safety monitoring after infusion, and there was immune reconstitution to CMV and EBV 4 weeks after CTL infusion as measured by IFN-γ ELISPOT (Enzyme-Linked ImmunoSpot) assay. Immune responses to adenovirus were only detected in patients with a reactivation or infection. Twenty viral reactivations were observed in patients before or immediately after CTL infusion. Nine of the 11 patients with CMV reactivation cleared CMV viremia without pharmacotherapy, with a corresponding rise in CMV-specific CTLs in peripheral blood [22,56]. An additional patient cleared with a combination of CTLs and ganciclovir while the final patient failed to respond to any treatment modality. Each of the six patients with high EBV loads cleared their virus, as did five of six patients with adenoviral infection [22]. This study demonstrated that multivirus-specific CTLs derived from the peripheral blood of seropositive donors were able to expand in vivo and mediate activity against multiple viruses from a single product. More recently, rapid multivirus CTLs generated using DCs nucleofected with DNA plasmids were administered to 10 allogeneic HSCT recipients with a response rate of 80%, including two patients with EBV lymphoma and three with double viral reactivations [57].

Adenovirus/EBV

Another trial by this group targeted recipients who received HSCT from CMV-seronegative donors. In this study, a chimeric adenovirus-specific vector alone (Ad5f35) was to modify monocytes and EBV LCLs, to generate a single culture of PBMCs that gave rise to CTLs specific for EBV and adenovirus [58]. Fourteen patients received bivirus-specific CTL after HSCT with no infusion-related toxicity and no patient developed more than grade II GVHD. All three patients with high EBV loads cleared their virus, as did two of three patients with adenoviral infections/disease, suggesting that this strategy is also efficacious and safe when used in the prophylaxis or treatment setting [58].

Table 68.2 Clinical trials using transplant donor-derived multi virus-specific CTLs for prophylaxis or treatment of viral infections

Virus	No. of patients	Transplant patient population	Type of CTL	GVHD	Antiviral effects	Ref.
CMV, EBV, and adenovirus	23 on study 3 emergency use or compassionate	Allogeneic HSCT recipients at risk of or with CMV, ADV, or EBV reactivation or disease	Activated by monocytes and LCLs transduced with adenoviral vector encoding CMV pp65	2 patients developed skin rashes that responded to topical steroids	6/6 with EBV cleared infection 5/6 with adenovirus cleared infection 10/11 with CMV cleared infection. 1 patient with CMV had disease that progressed despite CTLs and pharmacotherapy	Leen et al. 2006 [22] Bollard et al. 2011 [56]
CMV, EBV, and adenovirus	10	Allogeneic HSCT recipients with CMV, ADV, or EBV reactivation or disease	Activated by DCs nucleofected with DNA plasmids encoding viral antigens for EBV (LMP2, EBNA1, BZLF1), adenovirus (hexon, penton), and CMV (pp65 and IE1)	1 with skin rash possibly GVHD, possibly BK infection	CR in 2/3 EBV reactivation (including 2 with EBV-PTLD) CR in 4/5 CMV CR in 5/5 adenovirus	Gerdemann et al. 2013 [57]
EBV and adenovirus	12 on study 2 compassionate	Allogeneic HSCT recipients at risk of or with ADV or EBV reactivation or disease	Activated by monocytes and LCLs transduced with adenoviral vector	3 patients developed skin rashes that responded to topical steroids	11 patients treated as prophylaxis remain negative 2/3 patients with adenovirus cleared the infection	Leen et al. 2009 [58]
CMV and adenovirus	40	Allogeneic HSCT recipients at risk of CMV reactivation	Activated by adenoviral vector encoding CMV pp65	Grade II–IV acute GVHD occurred in 24% of the CTL cohort vs. 18% of the controls	Fewer CMV reactivations than controls and only 1 patient required CMV-specific pharmacotherapyImmune reconstitution to CMV in CTL recipients	Micklethwaite et al. 2008 [23] Blyth et al. 2013 [59]
CMV and EBV	3	Haploidentical HSCT recipients with EBV or CMV reactivation or disease	Induced by DCs pulsed with EBV-LMP2, CMV pp65 and CMV IE peptides	1 grade I	*Treatment:* Cleared in 2/2 *Prophylaxis:* No infections in 1	Dong et al. 2010 [60]

EBV, Epstein–Barr virus; CMV, cytomegalovirus; ADV, adenovirus; DCs, dendritic cells; HSCT, hematopoietic stem-cell transplantation; GVHD, graft-versus-host disease; CR, complete remission.

CMV/adenovirus

Using the same chimeric adenovirus–CMV pp65 vector described above, Micklethwaite et al. transduced donor-derived DCs which were used to stimulate autologous PBMCs to stimulate and expand CMV- and adenovirus-specific T cells [23]. In a recent update they reported that CMV/adenovirus-specific T cells were administered to 40 adult patients after HSCT as prophylaxis any time after day 28 post-transplant [59]. No infusion-related adverse events were observed and they saw no significant difference in the incidence of acute or chronic GVHD or in the rate of CMV reactivation compared with concomitant controls who did not receive CTLs. However, they did observe a significant reduction in the percentage of patients who required CMV-directed antiviral therapy and in the total number of treatment days per patient in the cohort receiving CTLs [59].

CMV and EBV

Dong et al. reported three pediatric patients who received donor-derived T cells directed towards CMV and EBV after haploidentical donor transplantation [60]. T cells were generated using DCs pulsed with peptides directed towards LMP2, pp65, and IE1 epitopes. Two patients developed CMV viremia less than 32 days after HSCT and cleared the virus with tapering immune suppression and T-cell infusion. (60]. The third patient was treated prophylactically and remained virus free more than 14 months after transplantation.

Targeting EBV, adenovirus, CMV, BK virus, and HHV6

Recently, the group at Baylor College of Medicine reported a study where rapidly manufactured multivirus specific T cell single-cultures were administered to 11 patients after HSCT. The multivirus specific T cells recognized 12 immunogenic antigens from five viruses (EBV, CMV, Adenovirus, BK virus and HHV6). Eight of the 11 patients had up to four active virus infections at the time of T cell infusion. These rapidly generated (10 days) T cell products were safe in allogeneic HSCT recipients and produced sustained virological and clinical response rates of 94% [75].

Risk of alloreactivity

In summary, these studies show that virus-specific T cells targeting one to three viruses have efficacy after HSCT to reconstitute immunity and clear viral reactivations and disease. Although the potential for de novo alloreactivity is a concern for all these approaches, the GVHD incidence did not appear to be increased over that which would be expected in the patient population (Tables 68.1 and 68.2). There was a particular concern in the mismatched setting as in vitro studies have shown that that a majority of virus-specific CTL lines possess cross-reactivity against allogeneic HLA molecules [61]. However, such alloreactivity was not observed among 153 recipients who received virus-specific CTLs, including 73 patients for whom there was an HLA mismatch with the donor [62]. The concern for alloreactivity, however, has meant that most studies have excluded patients with GVHD of grade II or greater.

CTLs for HSCT patients with virus-naïve donors

All of the donor-specific T-cell strategies discussed so far have utilized products derived from donors who are seropositive for the virus of interest. Adoptive transfer of virus-specific CTLs is currently not an option when the donor lacks viral immunity for the infecting virus or the recipient has received umbilical cord blood transplantation. Preclinical studies have evaluated circumventing this problem by transfer of artificial receptors specific for viral antigens [63,64]. but this strategy has not been tested in the clinic. There is also considerable interest in modifying culture conditions to reactivate CTLs from

Table 68.3 Clinical trials using third party virus-specific CTLs

Viruses targeted	No. of patients	Transplant patient population	Type of CTL	Serious adverse events possibly attributable to CTLs	Results	Ref.
EBV	2	HSCT recipients with PTLD	Closely matched allogeneic EBV-specific CTL	None reported	2 attained CR	Haque et al. 2007 [66]
EBV	5	HSCT including cord recipients with biopsy-proven PTLD	Closely matched allogeneic EBV-specific CTL	None reported	4 attained CR: 1 had progressive disease	Barker et al. 2010 [73] Doubrovina et al. 2012 [45]
EBV	1	Cord recipient with PTLD resistant to rituximab	Haploidentical GLC-peptide separated CTLs	None reported	1 attained CR Recurrence 9 months later responded to second infusion	Uhlin et al. 2010 [47]
CMV	2	Allogeneic HSCT recipients with CMV disease or viremia refractory to antiviral chemotherapy	Ex vivo stimulation with pp65 protein, followed by isolation of IFN-γ-producing cells	None reported	1 CR 1 failed to respond	Feuchtinger et al. 2010 [51]
Adenovirus	1	Unrelated HSCT recipient with intractable adenovirus infection	Gamma capture selected adenovirus-specific T cells from haploidentical donor	Liver GVHD (no third-party cells on biopsy)	1 CR	Qasim et al. 2011 [68]
EBV, CMV, and adenovirus	50	HSCT recipients with persistent CMV, EBV, or adenovirus despite standard therapy	Closely matched allogeneic trivirus-specific CTLs	Reactivation GVHD in 6 De novo GVHD in 2	Cumulative rate of complete or partial responses at 6 weeks post-infusion was 74% (73.9% for CMV, 66.7% for EBV, 77.8% for adenovirus)	Leen et al. 2013 [67]
EBV, CMV, and adenovirus	6	HSCT recipients with persistent CMV, EBV, or adenovirus despite standard therapy	Multimer selected T cells specific for CMV, EBV, and adenovirus	None reported	CMV: 3/4 responses Adenovirus: no response EBV: CR after second infusion	Uhlin et al. 2010 [47] Uhlin et al. 2012 [74]

HSCT, hematopoietic stem-cell transplantation; PTLD, post-transplant lymphoproliferative disease; GVHD, graft-versus-host disease; CR, complete remission; PR, partial remission.

virus naive donors [65] and a recent report demonstrates the feasibility of this approach clinically [76]. Finally several studies have evaluated whether third-party CTLs sharing HLA antigens with the HSCT recipient have activity against viral antigens, and studies evaluating this approach are summarized in Table 68.3.

Third-party EBV CTLs

One option that could provide an "off-the-shelf" product to all recipients is to use banked virus-specific T-cell lines generated from virus immune individuals with common HLA polymorphisms. Haque et al. used banked polyclonal EBV CTL lines to treat EBV PTLD after HSCT or solid organ transplantation in a phase II multicenter trial of 33 patients and reported an overall response rate of 52% at 6 months [66]. Investigators at the Memorial Sloan Kettering Cancer Center reported complete responses in four of five PTLD patients who received third-party EBV CTL lines [45]. In a multicenter study evaluating the use of third-party multivirus-specific CTLs to treat patients with refractory viral infections, the overall cumulative incidence of first complete/partial remission in 50 patients by day 42 after infusion was 74% (73.9% for CMV, 66.7% for EBV, and 77.8% for adenovirus) [67]. Although the response rates are slightly less than with donor-derived CTLs, this approach nonetheless shows considerable promise. Most studies have not shown an increased risk of GVHD, although there is one report of bystander-induced liver GVHD after third-party adenovirus CTLs [68]. If CTL banks are further developed, it will be important to establish criteria for HLA matching that would provide broad coverage, perhaps with the use of homozygous donors. A product targeting one virus may also have broader specificity than a multivirus line due to decreased antigenic competition during manufacture.

Cord blood-derived CTLs

With the increasing use of cord blood (CB) grafts, there are appreciable numbers of patients who are recipients of virus-naïve donor grafts. CMV reactivation usually occurs from endogenous virus, and seropositive recipients with seronegative donors remain the highest risk group for developing CMV. The development of multivirus-specific T cells from recipients of CB grafts requires the priming of naïve T cells rather than the simple expansion of preexisting memory T cells from seropositive donors. Using a protocol stimulating CB-derived T cells with autologous CB-derived DCs and EBV LCLs transduced with the Ad5f35CMV pp65 vector in the presence of IL-7, -12 and -15, multivirus-specific T cells can be primed in vitro from the 20% fraction of a CB unit [65]. So far, six patients have received CTLs as prophylaxis or treatment after CB transplant without toxicity [76]. No infusion-related toxicities/GVHD have been observed and, despite receiving only 80% of the CB unit, all patients engrafted neutrophils within 30 days. Early evidence of efficacy has also been demonstrated with clearance of EBV, CMV, and adenovirus in two patients with the other four patients remaining virus free. Although the study is ongoing, the results suggest that transfer of naïve T-cell (CB)-derived virus-specific T cells to patients after CB transplant may be safe and facilitate long-term reconstitution of virus-specific T cells in vivo.

Conclusions and future directions

Adoptive transfer of virus-specific CTLs can reconstitute viral immunity and treat viral infections that have failed to respond to conventional therapies. The overall response rate in HSCT recipients with active disease receiving donor-derived virus-specific CTLs from their transplant donors is around 80% (Tables 68.1 and 68.2) and around 70% for those receiving third-party cells (Table 68.3). In most cases the responses are durable so this strategy has many advantages compared with pharmacologic therapies. The broader application, however, has been limited by the complexity of some of the CTL manufacturing methodologies and the lengthy production time. Over the past few years, several groups have developed more rapid CTL generation protocols that appear to have equivalent activity and would allow definitive testing in late-phase trials.

CHAPTER 69

Adoptive T-cell Therapy for Malignancy in the Setting of Hematopoietic Cell Transplantation

Introduction

A variety of cellular therapies have been incorporated into the setting of hematopoietic stem-cell transplantation (HSCT). These include the infusion of polyclonal or antigen-specific T cells, lymphokine-activated killer cells, natural killer (NK) cells, dendritic cells (DC), and macrophages. The infusion of allogeneic T cells to enhance antitumor effects, referred to as donor lymphocyte infusions, is described in Chapter 70. The use of adoptive T-cell therapy to control infections and treat Epstein–Barr virus (EBV)-related tumors and other tumors induced by viruses is described in Chapter 68. In this chapter, we describe the background, rationale, and current clinical use and experimental approaches for adoptive T-cell therapies for the treatment of cancer in the setting of HSCT. Finally, we discuss the potential evolving with new cellular and molecular technologies that will likely influence the future directions, efficacy, and applicability of T-cell therapy.

History and rationale for adoptive T-cell transfer therapy

Background

The concept of adoptive cellular therapy for tumor allografts was first reported for rodents 60 years ago by Mitchison [1]. The cloning of T-cell growth factors made possible the first ex vivo expansion of tumor-specific T cells for adoptive immunotherapy in mouse syngeneic tumor models. There are several excellent reviews of the rationale and experimental basis for adoptive T-cell therapy of tumors [2,3]. In the earliest clinical trials, patients were given adoptive transfers of autologous, allogeneic, and xenogeneic lymphocytes for a variety of tumors. The results of these early trials were not promising, which is not surprising since they were carried out before the principles of T-cell biology and tumor antigens were understood. The field of adoptive cellular therapy during the first 25 years was reviewed by Rosenberg and Terry in 1977 [4].

Rationale

The seminal finding by Weiden et al. [5] that HSCT using sygeneic donors was less effective at preventing relapse of leukemia than the use of sibling donors provided a strong rationale for adoptive T-cell therapy. The rationale derived from that study is based upon the interpretation that the genetic differences provide alloimmune targets on tumor cells that passenger T cells from the syngeneic donor T cells are incapable of recognizing. Given the durable antitumor effects of T cells on human tumors, one could propose active immunization to boost T-cell numbers and function. However, there is now a broad consensus that therapeutic vaccines do not have the potency of approaches that are based on T-cell adoptive transfer. This is particularly true in the setting of hematopoietic cell transplantation (HCT) with the accompanying immunosuppression with quantitative and qualitative defects in T cells that can persist for months and years after the procedure [6], presenting a formidable obstacle to successful vaccine-based immunity.

Principles of T-cell transfer

Some considerations of basic immunologic principles as they apply to T-cell transfer in the setting of HSCT are presented in Table 69.1. Rational use of adoptive T-cell therapy is predicated upon an understanding of the relevant principles of cellular and molecular immunology and cancer cell biology. The reasons for the disappointing efficacy of many previous forms of adoptive cellular therapy are now clear based on lessons from advances in the basic sciences.

The typical host conditioning in HSCT presents challenges for active (vaccine) immunotherapy due to the depletion of lymphocytes. In contrast, host conditioning that renders the host lymphopenic creates an attractive setting for T-cell transfer because the engraftment and expansion of adoptively transferred T cells are facilitated under these conditions. There are many factors that lead to homeostatic expansion [7], and the expansion is accompanied by the acquisition of enhanced effector function [8].

During steady-state lymphopoiesis, the total lymphocyte count remains stable. However administration of cytokines from the common gamma chain family such as interleukins IL-2, IL-7, and IL-15 can increase total T-cell numbers above baseline levels. However, T cells, unlike B cells, are regulated at the clonal level [9], so that the adoptive transfer of large numbers of T cells with a single T-cell receptor (TCR) specificity may not result in long-term and high-level persistence of the adoptively transferred clones.

The optimal composition of adoptively transferred T cells remains controversial. Furthermore, it is likely that the best cell products vary depending on the tumor and goals of the adoptive

Table 69.1 Strategies to augment efficacy of adoptive T-cell therapy

Adjuvants to promote maintenance of Th1 cell function
Antibody infusions to enhance 4-1BB, CD27, or ICOS signals
Check point blockade: CTLA-4, PD-1, HVEM, LAG3, TIM3
Choosing the best cells: Tcm, Tn, Th17
Cytokine administration, for example, IL-7, IL-12, IL-15, IL-18, or IL-21
Cytokine antagonists, for example, TGF-β blockade or inhibition
CD4⁺ Th cell infusion to sustain CTL function
Enhance replicative capacity of infused cells
Host lymphodepletion
Host Treg-cell depletion or inhibition
Improving T-cell receptor affinity
Non-myeloablative stem-cell transplantation to facilitate allogeneic T-cell transfers
Tumor bed manipulation, for example, chemotherapy, chemokine expression in tumor bed to promote CTL trafficking cryoablation, phosphodiesterase-5 inhibition
Vaccine therapy to boost CAR T cells

therapy. For many years, it was thought that effector T cells were preferred. However, there is now evidence indicating that infusion of naïve T cells [10], central memory T cells [11], Th17 cells [12], and T stem cells [13] may all have certain advantages. In cases where the eradication of large tumors is desired, the optimal T cell is probably different to that when the goal is long-term persistence and immunosurveillance.

It is possible that previous clinical adoptive T-cell therapy clinical trials have been unsuccessful because the prolonged ex vivo culture process resulted in a population of cells that had reached, or were near, replicative senescence. Preservation of telomere length and replicative capacity correlates with the engraftment efficiency and antitumor efficacy of adoptively transferred T-cell lines in patients with melanoma [14]. CD28 stimulation maintains telomere length in T cells [15], and cultures that optimize costimulation might improve the engraftment and persistence of adoptively transferred T cells. Studies indicate that IL-15 induces a sustained level of telomerase activity and this minimizes telomere loss in memory $CD8^+$ T cells after a substantial number of cell divisions [16]. Constitutive expression of hTERT can extend the replicative potential of human T cells [17].

Genetic engineering of T cells has the potential to augment function through various cell autonomous mechanisms, as discussed above. In addition, T cells can be engineered for resistance to cell extrinsic forms of immunosuppression such as mediated by transforming growth factor beta (TGF-β) and regulatory T (Treg) cells [18,19]. Therefore, as with other forms of immunotherapy, it is probable that the ultimate clinical application of adoptive T-cell transfer will employ combinatorial approaches.

Strategies for T-cell culture and engineering

Rationale

For many years, the approach used by most investigators was based on the transfer of large numbers of effector T cells. This was necessary because the infused T cells were essentially non-replicative, and functioned essentially as drugs rather than as persisting memory T cells. Based on recent results in trials with engineered T cells [20,21], we now propose that in most cases, the infusion of small numbers of cells may be suffice, and that the most of the T-cell expansion can occur in the host rather than ex vivo in cell culture. One exception to this new approach may be in the setting of transiently engineered cells such as mRNA transfected T cells that require large numbers of cells to be infused on multiple occasions [22,23].

Approaches for T-cell culture

Studies indicate that, on a per cell basis, the adoptive transfer of T cells with extensive replicative capacity had improved engraftment and antitumor effects rather than transfer of terminally differentiated effector cells that have a more potent cytotoxic effector function [14]. This paradox is likely explained by the ability of central memory T cells (T_{CM} cells) to self-renew and differentiate into effector T cells in vivo, whereas terminal effector memory T cells (T_{EM} cells) have lost this plasticity. A controversy has arisen in the field regarding how best to achieve this goal [24]. One approach is to isolate T_{CM} cells with the desired specificity in vitro by sorting or other means of physical separation, engineer the desired specificity, and expand and then infuse the T_{CM} cells [11]. We have proposed that manipulation of bulk T-cell culture conditions can enrich and maintain T_{CM} cells, and thereby obviate the need for cell sorting procedures. Cell culture conditions that augment CD28 and CD137 (4-1BB) costimulation in vitro promote the maintenance of T_{CM} cells in vitro [25,26] and in vivo [27]. The use of memory stem cells, that is, T cells programmed for the most extensive self-renewal, has significant potential [13,28].

Two basic approaches are being tested for clinical adoptive T-cell therapy. The first approach has been to isolate and activate in vitro antigen-specific T cells from peripheral blood or tumor specimens, and then to use repetitive stimulation to expand clonally in vitro the antigen-specific T cells by various approaches. In the second approach, polyclonal ex vivo activation of the T cells is done based on three assumptions: first, tumor-specific T cells are present in the patient; second, the tumor-specific T cells have been primed in the patient; and third, the in vivo function of the tumor-specific T cells in the patient is impaired. In the second approach, the cells are activated in a polyclonal fashion by various means in vitro, and are then reinfused into the patient with the expectation that they will respond directly to the tumor or to tumor antigens presented by antigen-presenting cells (APCs). The first approach guarantees antigen specificity but is costly and labor intensive; the second approach is technically more rapid and feasible. In practical terms, only the second approach has been sufficiently robust to support randomized clinical trials [29,30], and therefore has the potential for regulatory approval.

The most appropriate methods of ex vivo T cell culture mimic the physiologic processes whereby DCs generate a constellation of antigen-specific and costimulatory signals in the T cells. However, although useful for therapeutic vaccination, owing to practical considerations such as substantial manufacturing costs and the logistics of maintaining independent culture systems, DCs are not useful as APCs for large-scale adoptive T-cell therapy trials. The optimal cell culture system varies depending on the T-cell subset that is propagated (Figure 69.1). General approaches have been to produce artificial APCs, either by coating beads with CD3-specific antibody or peptide–major histocompatibility complex (MHC) complexes, or by transfecting cells that lack endogenous MHC molecules with MHC molecules and costimulatory molecules.

Approaches for T-cell engineering

Advances in basic science have presented a plethora of approaches to engineer lymphocytes at the genomic, RNA, epigenetic, and protein levels, with the goal of pharmacologically enhancing the immune system [31]. An overview of permanent and transient strategies for engineering T cells is shown in Figure 69.2 and Table 69.2. For T cell-based therapies, chromosome-integrating vectors that are derived from gamma retroviruses or lentiviruses

Figure 69.1 Cell culture approaches for adoptive transfer of lymphocyte subsets. Culture conditions required for distinct lymphocyte subsets vary, depending on the activation and costimulatory requirements. CTLs express αβ TCRs and are stimulated by APCs that express MHC class I. CTLs require 4-1BB stimulation for expansion, and have been expanded by the addition of feeder cells or artificial APCs (aAPCs) that express the costimulatory ligands. CD4 T cells are stimulated by APCs that express peptide-loaded MHC class II. The dominant costimulatory molecule for CD4 cells is CD28. Effector CD4 cells can be stimulated by beads or cell-based aAPCs in the presence of various cytokines. Regulatory CD4 T cells (Treg cells) require culture in IL-2, and the addition of number of reagents to the culture may enhance the suppressive functions of ex vivo expanded Treg cells. Figure 69.2 T cells can be engineered to have retargeted specificity for tumors. (a) Endogenous T cells express a TCR with a single specificity. Bispecific T cells are created by the introduction of genes that encode proteins that recognize antigens expressed by target tumor cells. (b) These genes can encode natural TCRs that function in the same MHC-restricted manner as endogenous TCRs but have tumor-antigen specificity. (c) Alternatively, these genes can encode chimeric tumor antigen–specific receptors (CARs) that target surface antigens in an MHC-independent fashion. T bodies express an extracellular ligand generally derived from an antibody and intracellular signaling modules derived from T-cell signaling proteins. (For a color version of this figure, please see the color plate section.)

Table 69.2 Approaches for engineering lymphocytes

Approach	Advantages	Disadvantages	Use in the clinic	Ref.
Virus-based approaches				
Gammaretrovirus vectors	Extensive safety profile with 2 decades of clinical use	Insertional oncogenesis documented after infusion of engineered hematopoietic stem cells Poor efficiency for modifying other subsets of lymphocytes such as NK cells Deliver smaller DNA sequences than lentiviral vectors Susceptible to silencing, particularly in HSCs Require induction of cell division for integration	Extensive clinical use	[32]
Lentivirus vectors	High transduction efficiencies Transduce quiescent T cells	Increased production costs compared with gammaretroviral vectors Potential genotoxicity owing to LTR sequences and HIV accessory genes; third-generation self-inactivating vectors have improved safety following removal of these sequences	Early-stage clinical trials with engineered T cells using VSV-G pseudotyped lentiviral vectors	[33]
Spumavirus vectors or foamy virus vectors	Non-pathogenic in humans following zoonotic infection Favorable integration pattern compared with gammaretrovirus-based and perhaps lentivirus-based vectors	Clinical-grade vector manufacturing not yet available	Not yet reached the clinic; foamy virus-mediated insertion of CD18 into HSCs corrected congenital CD18 deficiency in dogs	[129]
Ad5/F35 vectors	Recombinant Ad5/35 vectors, which use CD46 as an entry receptor, efficiently infect human T cells and permit high level transgene expression for about 1 week Potential to introduce plasmids and antigens into T cells to generate T cells that can function as APCs	Lymphocytes express low levels of the Ad5 receptor, so are refractory to infection; vector tropism can be modified through manipulation of Ad5 fiber protein	Ongoing clinical trial with modified $CD4^+$ T cells for HIV infection (ClinicalTrials.gov NCT00842634).	[130]
Lymphotropic herpesvirses (HHV6 and HHV7)	Infect nearly all humans during childhood, with low pathogenicity Large payload capacity Transferred genes expressed efficiently in T cells	Clinical-grade vectors not yet produced.	Proposed for use in gene transfer and vaccine therapy	[131]
Non-virus-based approaches				
Random integration with electroporation	Efficient short-term expression of transgenes; long-term expression achieved in rare cells	For long-term expression, need to select and expand the rare T cells with integrated DNA in culture, leading to replicative senescence	Clinical trial with a CD20-specific CAR successful and resulted in engineered T cells with suboptimal engraftment and antitumor effects	[68]
mRNA transfection	Efficient expression in T cells Less expensive than virus-based vectors	Short persistence of transgene may require multiple T-cell infusions	Clinical trial with mesothelin CAR ongoing (ClinicalTrials.gov NCT01355965)	[22]
Transposon- based integration	A larger payload than retrovirus vectors High-level, persistent transgene expression Reduced cost compared with virus-based vectors	Tests needed to determine the safety and genotoxicity relative to lentivirus vectors	Clinical trial with CD19 CAR ongoing (ClinicalTrials.gov NCT00968760)	[87]
Genetic editing	Can selectively increase or decrease potency of T cells	Early in development but zinc finger nucleases and crispr/cas appear promising	Clinical trial with ZFN modified CD4 cells in HIV/AIDS	[145]

have been most useful for long-term gene expression because of their ability to integrate into the host genome, a feature that can result in permanent expression of the transgene, and for their low intrinsic immunogenicity [32,33].

For some applications, genomic alteration of adoptively transferred lymphocytes may not be required to achieve substantial therapeutic effects. RNA-based electroporation of lymphocytes using in vitro-transcribed mRNA mediates transient expression of proteins for approximately 1 week, and redirected T cells transduced with RNA encoding TCRs or chimeric antigen receptors (CARs) have the expected gains of function [22]. Clinical trials using mRNA-transduced DCs have been safely conducted [34] and trials using mRNA-electroporated T and NK lymphocytes are ongoing at several centers.

Clinical approaches in the setting of HSCT

Tumor-infiltrating lymphocytes

The adoptive transfer of tumor-infiltrating lymphocytes (TILs), expanded from resected melanoma specimens and selected for reactivity with tumor-associated peptides displayed by MHC molecules on cancer cells, can mediate durable tumor regression in a subset of patients with advanced metastatic melanoma [35]. A major advance was the recognition that host immunoablation could enhance the engraftment and efficacy of adoptively transferred T cells in melanoma [36] and lymphoma [37]. In non-controlled sequential trials, TIL therapy in the setting of autologous HSCT with high-dose chemotherapy and total body irradiation appears superior to TILs given with less intense host immunosuppression [35]. Technical issues with producing tumor-specific T cells currently present a formidable barrier to conducting randomized clinical trials using TILs.

Cytotoxic T-lymphocyte (CTL) therapy

MHC class I restricted CTLs are effective for viral infections and malignancies; see Chapter 68 for the use of CTLs for viral disorders. A dearth of tumor-associated antigens that are common to human tumors of a given type initially stymied investigators, preventing them from generating tumor-specific CTL populations. However, at present there is a plethora of suitable CTL targets for many

Table 69.3 Potential antigenic targets for CTL therapy

Antigen class	Example [Ref.]
1. Tissue-specific differentiation antigens that are not tumor-specific but may be selected as targets if injury to the normal tissue is tolerable, such as mesothelin in pancreatic cancer and prostate-specific antigen in prostate cancer	[132,133]
2. Cancer-testes (germ cell) antigens, such as NY-ESO-1 and the MAGE family, that are detected in many tumors, such as myeloma and melanoma, but not in normal adult tissues with the exception of the testes	[134,135]
3. Overexpressed self-proteins, particularly those associated with driver mutations, such as c-erbB2 in breast cancer	[136]
4. Mutational antigens that are tumor specific, such as $\text{BRAF}_{\text{V600E}}$ mutations and BCR-ABL translocations	[137]
5. Viral antigens that are tumor specific, such as EBV in Hodgkin disease, human papillomavirus in cervical cancer, and polyomavirus in Merkel cancer	See Chapter XX
6. Minor histocompatibility antigen (mHA)-specific T cells (allogeneic T cells)	[138]
7. Target tumor suppressor genes such as WT1	[139]

tumors [38]. The antigenic targets for T-cell therapy can be classed into six major categories (Table 69.3). All six classes of antigens shown in Table 69.3 have been targeted with acceptable safety with therapeutic vaccines; however, it is likely that only tumor-specific targets will have an acceptable therapeutic index with adoptive transfer of potent CTLs that have high-affinity TCRs. It is possible that conditional suicide systems expressed in self-reactive CTLs may increase the therapeutic index of CTLs in the setting of HSCT [39].

Improved CTL cell culture technology [40] permitted the first clinical tests of adoptive transfer of CTLs, and the approach seems to have substantial activity in patients with melanoma, although so far there has been limited efficacy outside of the setting of melanoma. For example, CTLs derived from peripheral blood lymphocytes (PBLs) were used to treat patients with refractory, metastatic melanoma [41], and the in vivo efficacy of the infused T-cell population was indicated by the destruction of normal melanocytes and outgrowth of a MART-1$^-$ tumor, demonstrating the selection of a tumor variant with loss of MART-1 expression [42]. Potent antileukemic effects have been observed in patients relapsing after allogeneic HSCT when minor histocompatibility antigen (mHA)-mismatched donor T cells are infused [43]. Perhaps the most worrisome issue revealed with CTL transfers is the emergence of antigen escape variants, which seems to be more common in human tumors than mouse syngeneic tumor models [44].

Combination approaches using vaccines and adoptive T-cell transfer

In mice, adoptive T-cell therapy enhances the effects of therapeutic vaccines [45], and this combined approach in the setting of lymphopenia results in a further enhancement of tumor immunity [46,47]. In humans with myeloma, idiotype vaccination of sibling donors with the unique tumor-specific immunoglobulin produced by the patient myeloma cells followed by adoptive transfer in the setting of allogeneic stem-cell transplantation can result in the induction of potent antitumor immunity [48].

Several phase I clinical trials using adoptive transfer of autologous activated T cells in patients transplanted for hematologic malignancies have been reported. In the first trial [37], patients with relapsed or chemotherapy-refractory non-Hodgkin lymphoma (NHL) were given a CD34$^+$ HSC transplant followed by infusion of autologous T cells expanded ex vivo with CD3- and CD28-specific antibodies. Infusion of the autologous costimulated T cells resulted in a rapid reconstitution of lymphocyte numbers. Importantly, the expanded cells were functionally superior to those obtained directly from the patients, as determined by their ability to produce interferon-gamma (IFN-γ) when stimulated with tumor cells in vitro. In a second randomized trial, the feasibility of pre-transplant immunization and adoptive transfer of vaccine-primed T cells in the setting of autologous transplantation for multiple myeloma was tested [29]. Patients were vaccinated with Prevnar, the heptavalent pneumococcal conjugate vaccine (PCV), and 2 weeks later T cells were harvested and expanded in vitro using CD3- and CD28-specific antibodies. Patients received a standard autologous peripheral blood HSC transplant after melphalan conditioning, the ex vivo expanded autologous T cells either 14 or 100 days post-transplant, and two doses of PCV, beginning 1 month after transplant. Prompt T-cell recovery was observed in patients who received ex vivo expanded autologous T cells 14 days after the HSC transplant, whereas those who received the T cells 100 days after the transplant remained substantially lymphopenic. Early adoptive transfer of PCV-primed T cells resulted in the induction of potent immunity, as only those individuals who received PCV-primed T cells soon after the transplant developed and maintained protective levels of pneumococcal-specific antibodies, as well as vaccine-specific CD4$^+$ T-cell responses. Similar trials have shown that the combination of adoptive transfer and vaccination can induce potent humoral and cellular response to human telomerase reverse transcriptase (hTERT) and influenza in patients with advanced myeloma autologous HSCT [30,49]. In the setting of autologous HSCT for pediatric neuroblastoma, adoptive transfer of T cells given on day 2 were superior to infusions given on days 12 or 90 after stem-cell infusion when TCR repertoire diversity and the humoral response to a pneumococcal vaccine were assessed [50].

The primary toxicity of combined T-cell transfer and vaccine strategies has been an autologous graft-versus-host disease (GVHD)-like syndrome with rash and colitis in about 25% of patients [51]. These data demonstrate that a combination of vaccine and adoptive T-cell therapy, consisting of a single pre-transplant vaccine and an early post-transplant infusion of in vivo antigen-primed, ex vivo-costimulated autologous T cells followed by post-transplant booster immunizations, improved the severe immunodeficiency associated with high-dose chemotherapy, and led to clinically relevant immunity in adults within 1 month of HSC transplantation, in contrast to the 1 year that is required to reconstitute immunity following a standard transplant procedure [6]. These studies provide a useful foundation for the design of future strategies using combinations of tumor vaccines and vaccine-primed T cells in lymphodepleted patients with various malignancies.

Synthetic biology with engineered T cells

Rationale

The high level of tolerance to most tumor antigens combined with immunosuppressive microenvironments supports the conclusion that augmentation of immunity with adoptive transfer of T cells may not be sufficient in most patients with advanced malignancy. An emerging discipline is synthetic biology, which combines elements of engineering, chemistry, computer science, and molecular biology to assemble cellular and biological tools necessary to improve the natural function [52]. The principles of gene transfer combined with adoptive cellular therapy are poised to overcome these limitations.

Genetic modification of T cells to engineer improved antitumor effects and enhanced immune reconstitution of immunosuppressed patients is an attractive strategy in many settings [53]. A potential safety concern when infusing individuals with engineered T cells is one that arose with genetically engineered HSCs [54], when viral insertional mutagenesis was shown to cause cellular transformation. However, in patients with congenital and acquired immunodeficiency, genetically modified T cells have been shown to persist after adoptive transfer in humans for more than a decade without adverse effects [55,56], indicating that the approach to genetically modify mature human T cells is fundamentally safe.

Strategies

To overcome tolerance to tumors that results from deficiencies in the TCR repertoire, two approaches are being developed. In the first approach, TCR genes are isolated from tumor-reactive T-cell clones, assembled in gene transfer vectors, and introduced into T cells from a patient of the appropriate MHC type to confer tumor specificity. In the second approach, genetic modification of T cells is accomplished with CARs containing sequences that encode antibody-based recognition domains linked to signaling sequences. An advantage of CARs is that since they are specific for cell surface molecules, this overcomes the constraint of TCR recognition of peptide antigens presented by only certain MHC molecules, and avoids tumor escape through impairments in antigen presentation or HLA expression. Genetic modification of T cells is not limited to conferring new antigen reactivity to recipient T cells, but can also be used to insert genes that improve the efficacy of the T cells that are transduced. Such genes include those encoding molecules involved in costimulation [57], the prevention of apoptosis [58], the remodeling of the tumor microenvironment [59], the induction of homeostatic proliferation [60], and CARs encoding chemokine receptors that promote T-cell homing [61].

Clinical trials with CAR T cells

The design of CARs in clinical trials can be roughly classified into three generations. First-generation CARs encode antibody-based external receptor structures and cytosolic domains that encode signal transduction modules comprised of the immunoreceptor tyrosine-based activation motif such as TCRζ or FcRγ [62]. Second-generation CARs also include a costimulatory signaling domain such as CD28 or 4-1BB [63,64], and third-generation CARs include three or more cytosolic domains [65].

First-generation CARs

The first CAR trials were conducted in patients with HIV. Two phase I and one phase II trial testing a first-generation CD4ζ CAR were reported [66]. The trials demonstrated modest antiviral efficacy; however, the CD4ζ CARs T cells have persisted at high frequency in most patients. Encouragingly, retroviral integration site analysis showed no evidence of persistent clonal expansion or enrichment of integration sites near oncogenes or tumor suppressor genes [56].

Several phase I clinical trials were conducted in patients with cancer. A trial testing T cells expressing a CAR specific for a folate-binding protein that is present on ovarian carcinoma cells indicated that the approach was safe, but poor expression and persistence of the transgene encoding the CAR were observed in vivo [67]. Similarly, a pilot test in children with neuroblastoma treated with autologous T cells retargeted for a tumor-associated adhesion (CD171) molecule indicated that the approach is safe but was limited by poor persistence of the T cells [68]. Lamers et al. tested T cells expressing a CAR receptor specific for carbonic anhydrase IX, an antigen present on the surface of clear cell renal cell carcinoma [69]. They observed an unexpected serious hepatic toxicity in several patients within 1 week of T-cell infusion, which was due to carbonic anhydrase IX expression in the biliary tract. This study indicates that CAR T cells can traffic to and exert effector function at sites of antigen expression. Furthermore, it indicates that the targets of chimeric antigen receptors must be carefully chosen to avoid unwanted adverse effects, or that additional safety features, such as suicide switches [70], need to be incorporated into the vectors driving the expression of the chimeric receptor. In several instances, the engineered cells persisted for several weeks before elimination by host immune responses, indicating that a technical challenge for this approach is to prevent a host immune response from eliminating the adoptively transferred cells.

One of the lessons from the trials testing first-generation CARs T cells was that the infused product could be immunogenic. Both B-cell [67,69] and T-cell responses [71,72] have been identified in CAR trials. In the trial by Lamers et al., the plasma from these patients neutralized target cell recognition by the CAR T cells. In addition, they have shown [72] that 8/9 evaluable patients also developed cellular immunity against their carbonic anhydrase IX-specific CAR, and that patients who developed a B-cell response against the CAR also exhibited a cellular response against CAR T cells, but not necessarily the other way around.

Another lesson from the trials testing first-generation CARs in cancer trials was that the persistence and expansion were poor. This is likely the result of CAR design in part, and the use of suboptimal cell culture approaches that favored terminally differentiated T_{EM} CAR products rather than T_{CM}. The best persistence of CARs reported was in the pediatric neuroblastoma trial (ClinicalTrials.gov NCT00085930), where CARs could be detected at very low levels (0.0001–0.001%) at up to 4 years after infusion [73]. In contrast, in the CD4ζ CAR trial (ClinicalTrials.gov NCT01013415), the frequency of CAR T cells in blood was several orders of magnitude higher (0.6–6%) in patients 5 years after infusion [56].

A final lesson from the first-generation CAR trials in cancer patients was that efficacy was disappointing. The best clinical results were reported in patients after infusion of a GD2-specific CAR, with two of 11 patients having long-term remissions [73].

Second- and third-generation CARs

For ethical reasons, it was necessary initially to evaluate first-generation CARs to exclude safety concerns such as the induction of a T-cell lymphoproliferative syndrome. Based on principles of T-cell activation [74], it would be predicted that that the first-generation CARs would become anergic unless the tumor target provided costimulation [19]. In addition, resting T cells cannot be activated with CAR containing a TCRζ or FcRγ signaling moiety in the absence of costimulation [75]. In 1998, two laboratories showed that the CD28 signaling domain provided costimulation when engineered into the CAR design, in cis with the TCRζ domain [63,76]. It was later shown that members of the tumor necrosis factor receptor family such as CD27, 4-1BB (CD137), and OX40 (CD134) also provided costimulation [77–79]. These second- and third-generation CARs are now in a number of early-stage clinical trials at academic medical centers.

CAR trials targeting B-cell malignancies

Other than normal B cells, CD19 is not present on normal tissues including pluripotent blood stem cells, and is not shed as a soluble form into the circulation, which makes CD19, or CD20 as evidenced by rituximab, a relatively safe target presenting a minimal risk of autoimmune disease or irreversible myelotoxicity. Many trials are currently ongoing to test second- and third-generation CARs (reviewed in [80,81]). Promising results have been obtained targeting the B-cell lineage-restricted CD19 molecule that is expressed on B-cell leukemias and lymphomas with CD19-specific CAR T cells [20,82–84]. At the University of Pennsylvania, durable remissions beyond 2 years have been observed in the initial cohort of patients with refractory and relapsed B-cell chronic lymphocytic leukemia (CLL) after the infusion of autologous T cells transduced to express a CD19-specific CAR that contained a 4-1BB costimulatory domain [20,21]. In these studies, the infusion of low doses of T cells led to 2–4 log10 in vivo expansion and persistence of CAR T cells, subsequent tumor lysis, and a persistent aplasia of normal CD19$^+$ B cells [20]. Significant antitumor activity, depletion of normal B cells, and side effects related to tumor lysis and cytokine release have also been reported in patients with CLL and lymphoma by groups at the National Institutes of Health, Memorial Sloan Kettering Cancer Center, and Baylor College of Medicine in trials in which autologous T cells were modified to express CD19 CARs that contain a CD28 costimulatory domain [82–85]. In addition to activity in CLL and mantle cell lymphoma [20,65], CD19:4-1BB CARs have potent activity in pediatric acute lymphoblastic leukemia (ALL) with efficient trafficking to bone marrow and cerebral spinal fluid [86]. It is currently unknown whether CARs with a CD28 or 4-1BB signaling domain are preferable. A clinical trial led by Brentjens and colleagues infusing an equivalent number of CD19-specific CARs containing either a CD28 or 4-1BB domain is ongoing to address this issue (ClinicalTrials.gov NCT01044069).

The above trials employed efficient retroviral or lentiviral transduction to introduce CARs into T cells. Whether one vector is superior remains unknown. An ongoing trial (ClinicalTrials.gov NCT00968760) is testing CD19 CARs that are expressed using the *sleeping beauty* transposon system [87]. There are many other questions outstanding about the use of CARs for B-cell malignancies. In the area of CAR design, in addition to the open questions on optimal costimulatory domains, the optimal characteristics of the scFv (affinity and epitope), the hinge length, and transmembrane domain remain to be defined. In addition, there are major questions regarding clinical trial design, such as whether to provide cytokine support to the patient after CAR infusion and whether host conditioning chemotherapy is necessary.

Toxicity with CAR T cells

As with all cancer therapies that have efficacy, there is an emerging set of toxicities with CAR T cells. Many types of adverse events have been reported following infusion of human autologous or allogeneic lymphocytes. The toxicities can be classified as those due to extrinsic factors present in the culture process, those due to accompanying cytokines that can be co-infused with the cells, and those due to the cells themselves. The spectrum of the third form of adverse effects is still being defined, and for the moment seems to be related to whether the cell product is genetically engineered. For cell products that have not been genetically engineered, the adverse effects are limited and are similar to those observed with therapeutic vaccines. Retinitis, iritis, hepatitis, autoimmune thyroiditis with hypothyroidism, and vitiligo occur following autologous T-cell infusions [36,42,69,88]. Respiratory obstruction has been reported following CTL infusion for EBV-related lymphomas [89]. This is probably due to a T-cell-induced inflammatory response that results in tumor edema and necrosis. Effector functions of infused T cells can be expected to include tissue damage similar to that encountered in T-cell-mediated autoimmune diseases. In the case of allogeneic lymphocyte infusions, GVHD and bone marrow aplasia can occur [90].

On-target toxicities were expected with CD19 CAR T cells and include B-cell aplasia, tumor lysis syndrome (TLS) and cytokine release syndrome (CRS). Intravenous immunoglobulin can be used to replace deficient antibody function. TLS has been managed successfully according to standard supportive therapy, including hydration, alkalinization, allopurinol, and rasburicase as required [91]. A unique feature of the TLS following CAR T-cell therapy is that this can be delayed for significant periods of time [21]. At the University of Pennsylvania, one patient developed fulminant TLS nearly 2 months following CAR infusion. In all cases, TLS is accompanied by fever and elevated levels of inflammatory cytokines such as IFN-γ and IL-6.

In patients with B-cell malignancies, CRS occurs at the time of peak levels of CAR T cells in blood and bone marrow. The optimal management of CRS is still an open question. Corticosteroids and cytokine blockade with etanerocept and tocilizumab are currently being evaluated for patients with ALL and CLL. A grading system for CRS was recently reported, and a clinical management algorithm was suggested [140]. On-target but off-organ toxicity to normal tissues remains an issue for which novel strategies to mitigate toxicity, such as by regulating CAR expression or T-cell survival, are needed.

A number of theoretic off-target toxicities with CAR T cells are possible. The introduction of CARs by integrating retroviral or lentiviral vectors, transposons, and electroporation all create the risk of transformation. This risk appears to be low based on the long-term follow-up data in patients treated with the CD4ζ CAR, where there have been no cases of genotoxicity in more than 540 patient-years of observation [56]. Another theoretic risk, particularly with CARs containing synthetic signaling domains, is the induction of a T-cell lymphoproliferative syndrome or T-cell leukemia. T-cell leukemia has occurred in the setting of retroviral-mediated gene transfer into HSC for congenital immunodeficiency [54]; however, it has never been reported following gene transfer into mature T cells. Finally, the risk of replication competent retrovirus (RCR) or lentiviruses exists, as this has occurred previously with severe consequences in non-human primates who were infused with HSC cells transduced with a retroviral vector containing RCR [92]. With improved packaging lines and plasmid design, this has not occurred following adoptive transfer of retroviral modified T cells in 297 humans enrolled in 29 different clinical protocols [93].

Clinical trials with transgenic TCR-modified T cells

A principal limitation of adoptive T-cell therapy for most cancer histologies is that the tumors are poorly antigenic or that the highest avidity T cells have been deleted during thymic selection; therefore, there are no T cells with high avidity for tumor-specific antigens and there may be no T cells with the desired specificity left in the patient after chemotherapy. Most T cells have TCRs of micromolar affinity for peptide–MHC ligands, but genetic engineering can generate TCRs of nanomolar affinity. Two approaches to improve the affinity of TCRs are now being tested in clinical trials. In one approach, mice that express both human MHC and TCR genes have been developed and can be vaccinated to elicit TCRs from a repertoire that is not tolerant to human self or tumor-associated determinants [94]. It is also possible by mutation to improve the affinity of TCRs obtained from low-avidity T cells specific for self-proteins [95]. The affinity for MHC class I TCR viral epitopes can be enhanced into the sub-nanomolar range, with improved clinical activity noted when the affinity-enhanced TCRs are expressed in T cells in preclinical studies [96]. However, the introduction of TCRs specific for self antigens that are of too high affinity can result in the deletion of transferred $CD8^+$ T cells in vivo, whereas $CD4^+$ T cells expressing the same TCR survived [97].

Clinical trials using TCR gene transfer to target differentiation antigens (MART-1, gp100, CEA) and the cancer-testes antigen NY-ESO-1 have been reported [98–100]. Some antitumor effects were observed and on-target toxicity to normal melanocytes in the skin, eye, and ear that required local corticosteroid therapy was observed in a significant fraction of patients who received the highest avidity TCRs. Consistent with this, the introduction of a high-affinity carcinoembryonic antigen (CEA)-specific TCR into autologous T cells to treat colorectal cancer resulted in severe colitis, presumably from recognition of normal epithelial cells that express CEA, and the trial was halted when stopping rules were reached after three patients [101]. These data, together with the CD19 CAR data showing persistent B-cell aplasia, indicate that for engineered T cells the therapeutic index is less than with natural T cells, and that only targets with highly restricted expression to tumor cells will have acceptable toxicity. Consistent with this notion, a TCR specific for an HLA A*0201 restricted NY-ESO-1 epitope, which is expressed in many human cancers but not in normal tissues apart from testes, was used to engineer autologous T cells for treatment of metastatic melanoma and synovial sarcoma. Objective responses were observed in five of 11 melanoma patients and four of six sarcoma patients without toxicity to normal tissues [100]. A phase II trial testing the same NY-ESO-1-specific TCR in myeloma patients that is ongoing at the University of Pennsylvania has also documented potent on-target antitumor effects without significant toxicity (ClinicalTrials.gov NCT01352286).

A concern with the transgenic TCR approach has been that it might generate additional, novel receptor specificities by pairing of the transgenes with the endogenous TCR chains, creating so-called "mixed dimers." In mice, a lethal GVHD syndrome can occur due to the formation of mixed dimers [102]. However, it is encouraging that no toxicity was observed in the above TCR trials that have together enrolled more than 50 patients. There are several potential solutions to address this concern. First, alpha beta TCRs can be transferred into gamma delta T cells, taking advantage of the observation that alpha and beta polypeptide chains do not pair with gamma delta TCRs [103]. Second, there are elegant approaches to prevent the endogenous TCR from pairing with the transgenic TCR. In one case, this was prevented by knocking down the expression of endogenous TCR chains using inhibitory RNA [104], and another approach to eliminate the problem of mispairing of TCR chains is to abolish expression of the endogenous receptors using specific zinc-finger nucleases that disrupt the endogenous TCR alpha and beta gene loci [105]. Serious off-tumor toxicity with engineered TCRs has occurred [141–143]. In addition, serious case of CRS occurred following the infusion of MART-1 modified T cells [144].

Incorporating CAR and TCR T cells into stem-cell transplant regimens

Genetically engineered T cells have the potential to augment the efficacy of autologous HSCT procedures. The antitumor activity of autologous CD19 CAR T cells in patients with advanced B-cell malignancies and TCR T cells in myeloma illustrates the potential to incorporate the administration of T cells modified with a CAR or TCR to reduce relapse after autologous stem-cell transplant. The importance of lymphodepleting chemoradiotherapy for improving the persistence and antitumor efficacy of transferred T cells was established in studies in melanoma and lymphoma [36,37], and this suggests that intensive conditioning administered before autologous HCT could provide an ideal environment for administering engineered T cells. Furthermore, in mice, mice effector $CD8^+$ T-cell function is enhanced by concomitant HSC infusion [106].

Leukemia relapse remains a major cause of failure after allogeneic HCT and the long-sought goal of augmenting the graft-versus-leukemia (GVL) effect without aggravating GVHD remains elusive [107]. It is possible that infusion of allogeneic TCR- or CAR-modified T cells could enhance the efficacy of allogeneic HSCT. This is supported by data that indicated that infusion of costimulated but non-gene-modified allogeneic T cells was safe in a phase I trial [108]. In that study, 18 patients with relapse after allogeneic SCT were given infusions of activated donor T cells costimulated with anti-CD3- and anti-CD28-coated beads. Patients were given adoptive transfer on day 12 after reinduction chemotherapy. Activated donor lymphocyte infusion (DLI) was dose escalated from 1×10^6 to 1×10^8 $CD3^+$ cells per kilogram in five levels. Seven patients developed acute GVHD (five grade I–II, two grade III), and four developed chronic GVHD. Eight patients achieved complete remission, including four of seven with acute lymphocytic leukemia, two of four with acute myelogenous leukemia, one with chronic lymphocytic leukemia, and one of two with NHL. Several trials are now under way to evaluate the safety and antileukemic potential of CAR-modified allogeneic T-cell infusions.

Strategies to use engineered T cells as a bridge to transplant

The development of CAR- and TCR-transduced T cells, specific for leukemia-related antigens, introduces the possibility of utilizing these cells in a variety of clinical circumstances important in transplantation. The first are for patients who have relapsed ALL and who are candidates for allogeneic transplantation. Given the limited therapeutic efficacy of reinduction regimens, the development of engineered T cells may provide an appropriate bridge to transplant by inducing a remission that can then be preserved by an allogeneic transplant. In patients who have undergone a transplant, it may be possible to utilize the CAR- or TCR-transduced T cells for treatment of either relapse that occurs after transplant, instead of DLI, utilizing an antigen-specific donor-derived immune response separate and distant from the allogeneic reactivity against leukemia cells mediated by DLI. In addition, as monitoring for minimal residual disease becomes more standardized and important, both in the management of patients pre-transplant receiving standard therapy and post-transplant, donor-derived CAR-transduced T-cell DLI could be utilized to treat molecular evidence of recurrent disease before overt relapse occurs. The possibility of utilizing viral-specific T cells as the transduced cell population can further reduce the likelihood of concomitant graft-versus-host reaction and may be manipulable by various vaccine strategies. These same principles could be extended to other target antigens as they evolve for both myeloid leukemias and also multiple myeloma.

In the autologous setting, there are fewer data available about the efficacy of these cells in the treatment of patients with recurrent B-cell lymphoma, although the antigenic determinants may be the same. Nevertheless, CAR-based T-cell therapy that facilitates a response, if not remission, in patients relapsing after standard therapy for large-cell lymphoma may also serve as a bridge to transplant. Similarly to the allogeneic setting, investigators could utilize CAR-transduced T cells specific for CD19 as post-transplant immunotherapy to help reduce the chances of relapse by introducing a CD19-specific T-cell reconstitution as part of the general immune reconstitution that occurs after transplant. Currently, trials are ongoing to address this approach in the post-transplant setting, both for lymphoma and also for multiple myeloma targeted to NY-ESO1, utilizing a TCR transduction strategy. Thus, chimeric antigen receptor-transduced T cells may have a role in the autologous setting in preparing patients for transplant or by augmenting the efficacy of transplant to prevent relapse after autologous transplant.

Moving to the dark side: adoptive therapy with T regulatory cells

Mature donor effector T cells cause GVHD, but they are also the main mediators of the beneficial graft-versus-tumor (GVT) activity of allogeneic bone marrow transplantation. Naturally occurring, thymic-derived Treg cells that express CD4, CD25, and the forkhead box protein 3 (FoxP3) are potent suppressors of GVHD and other immune responses. In mice, the infusion of freshly isolated or ex vivo expanded donor Treg cells was highly effective in preventing acute or chronic GVHD [109]. In a mouse model, the infusion of donor-derived Treg cells prevented GVHD without abrogating GVT effector function, an effect that was mediated primarily by the perforin lysis pathway [110]. Further, in vivo activated donor or host Treg cells were able to ameliorate ongoing chronic GVHD.

Clinical-scale culture technologies using rapamycin and artificial APCs (Figure 69.1) were developed at the University of Minnesota to expand efficiently naturally occurring regulatory T (nTreg) cells from donor peripheral blood or cord blood [111]. A trial tested nTreg cell infusion in patients receiving double umbilical cord blood (UCB) transplant demonstrated the safety and feasibility of the adoptive transfer of ex vivo expanded nTreg cells [112]. In this protocol, 23 patients received infusions of nTreg cells that were isolated from a third UCB unit, enriched, expanded ex vivo, and reinfused. The UCB nTreg cells engrafted and were detected in circulation for 2–14 days after infusion. The UCB trial demonstrated that expanded nTreg cells were safe up to a dose of 3×10^6/kg, meeting the primary end-point of the study. No infusional toxicity was observed, nor was there an increased risk of infection, relapse, or early mortality. Patients given adoptive transfer of nTreg cells had a reduced the incidence of grade II–IV acute GVHD (43% vs. 61%, $p = 0.05$) compared with 108 historical controls treated identically except for Treg cells [112].

Phase II trials are scheduled to test the safety and efficacy of nTreg cell adoptive transfer to prevent GVHD in patients at high risk for grade II–IV GVHD. The main issues to address are whether Treg cells decrease the GVL effect and lead to higher rates of tumor relapse or increase the risk of opportunistic infections. A theoretic concern is that in some models, Treg cell plasticity has been reported, and the Treg cells can lose Foxp3 expression and differentiate into pathogenic Th17 cells [113].

Dose and scheduling issues

Information on the dose and schedule dependence of adoptively transferred cells is widely scattered in the literature, and from this literature one concludes that there is no standardized dose system. There is, however, evidence from animal models in non-lymphopenic hosts suggesting that multiple doses of adoptively transferred T cells have superior antitumor effects to a single infusion of T cells [114]. Doses of adoptively transferred cells are usually reported as the total number of viable cells administered, or as the total number of viable cells administered per kilogram body weight or per square meter of body surface area. However, total endogenous lymphocyte numbers do not correlate well with body surface area, but rather display a strong inverse correlation with age. Other variables add to the complexity, particularly the fact that, in the case of T cells or other adoptively transferred cells with high replicative potential, the infused dose might not relate well to the steady-state number of cells that engraft and persist. Therefore, dose considerations are more complex than in other areas of transfusion medicine, where, for example, the maximal level of transfused red cells or platelets occurs immediately following infusion. In our studies of adoptively transferred autologous CAR T cells, we often find that the number of cells in the host peaks 2–3 weeks after infusion of the cells [20]. This is because the engraftment potential and the replicative potential of the infused cells depend on complex host variables such as the number of niches available in the host for engraftment, and the antigenic stimulus for clonal expansion or deletion. In most rodent tumor models, T-cell proliferation in the host after transfer is obligatory for therapeutic efficacy (reviewed in [2]) and, with rare exceptions where adoptively transferred effector T cells are used as a non-replicating drug rather than replicating cells [115], this is presumed also to be required in humans.

Cytokines given to the host can also have a major impact on the persistence of adoptively transferred T cells. Others have found that the persistence of adoptively transferred human $CD8^+$ T cells is enhanced by coadministration of IL-2 [116]. However, we have found that when autologous human $CD4^+$ and $CD8^+$ T cells are given in combination, persistence is not increased by concomitant IL-2 therapy [117]. Finally, studies have shown that IL-2 can induce the proliferation and maintenance of effector $CD8^+$ T cells but might actually delete memory T cells and increase the number of Treg cells [118]. By contrast, IL-15 and IL-7 seem to select for the persistence of memory $CD8^+$ T cells and might decrease the number of Treg cells in mice [119] and non-human primates [120].

Striking schedule-dependent increases in efficacy and the frequency of adverse effects from adoptively transferred cells have been reported when T-cell infusions are given to lymphopenic hosts [51,121,122]. Many studies in rodent tumor models show that the coadministration of cytotoxic therapy can enhance the effects of adoptively transferred cells [123]. Cyclophosphamide and/or fludarabine is generally administered to the host several days before the adoptively transferred T cells. The drugs have multiple effects that seem to promote the antitumor effects of the adoptively transferred T cells [7].

Curti et al. [124] studied the optimal time to harvest autologous $CD4^+$ T cells in relation to the timing of cyclophosphamide administration in patients with advanced cancers. T cells were harvested at steady state, or when on the decline or when on the recovery from the cyclophosphamide-induced leukopenia, and they found the greatest in vivo $CD4^+$ T-cell expansion after infusion occurred when cells were harvested as patients entered the cyclophosphamide-induced nadir. These findings are relevant to T-cell infusions post-HSCT. In a pediatric population, we find that infusion on day +2 is superior to day +12 or +90 after high-dose chemotherapy [50].

Conclusions and future directions

Adoptive T-cell therapy is the ultimate challenge to the implementation of personalized medicine, and is a natural extension of HSCT. The field of adoptive therapy with engineered T cells is poised for substantial clinical advances that are now possible because of improved cell culture and gene transfer methods. In some cases, engineered autologous T cells may be able to replace the need for allogeneic HSCT, so it is conceivable that autologous HSCT with T-cell infusions could reach the efficacy of allogeneic HSCT but without the risk of GVHD. However, the major challenge currently facing the field is to conduct randomized clinical trials demonstrating sufficient clinical benefit to justify the logistics and expense of customized cellular therapies.

Based on a more advanced understanding of lymphocyte development, another area of opportunity will be the infusion of engineered precursor cells that are programmed to have the functions of effector lymphocytes. Examples include the adoptive transfer of engineered common lymphoid progenitor cells [125], memory stem T cells [13,28], and "retrogenic T cells" produced by administration of embryonic stem cells or HSCs engineered to express transgenic TCRs or chimeric antigen receptors after in vivo differentiation to T cells [126–128].

CHAPTER 70

Relapse of Hematologic Malignancy After Allogeneic Hematopoietic Transplantation

Richard Champlin
The University of Texas M.D. Anderson Cancer Center, Houston, TX, USA

Introduction

Allogeneic hematopoietic transplantation is an effective, potentially curative treatment for hematologic malignancies. Advances in supportive care have markedly improved treatment-related mortality associated with the procedure, but relapse of the underlying malignancy remains a major problem and is the major cause of treatment failure [1–4]. The prognosis relates to the aggressiveness of hematologic malignancy, responsiveness to salvage chemotherapy, and immune manipulations of the graft-versus-malignancy effect.

Allogeneic hematopoietic transplantation involves the administration of high-dose chemotherapy and/or radiation with reconstitution of hematopoiesis by donor-derived cells. The high-dose therapy does not generally eradicate the malignancy, and the immune graft-versus-leukemia (GVL) effect is important to eliminate residual drug-resistant disease [5]. Evidence supporting this premise includes the higher rate of relapse in patients with identical twin donors and in those receiving T-cell-depleted transplants [6]. Natural killer cells are important in the process of GVL against myeloid leukemias [7,8] and may mediate GVL effects in T-cell-depleted transplants. Graft-versus-host disease (GVHD) remains a major obstacle to successful allogeneic hematopoietic transplantation. Calcineurin inhibitors and antithymocyte globulin have reduced the incidence and severity of GVHD, but the intensity of post-transplant immunosuppressive therapy may increase the risk of relapse [9,10]. The minor histocompatibility antigens involved in graft-versus-leukemia and graft-versus-host reactivity likely overlap [11] and patients with GVHD (particularly chronic GVHD) are less likely to relapse [6]. The major challenge in hematopoietic transplantation is to separate effectively the beneficial GVL effect from the toxicity of GVHD. Several approaches are under investigation aimed at augmenting the allogeneic graft-versus-malignancy effect while preventing GVHD.

Mechanism of relapse post-transplant

Relapse generally results from residual malignant cells that survived the preparative regimen and are not eliminated by the GVL effect. In a minority of patients, relapse appears to occur in donor-derived cells [12–14]. The diagnosis of donor cell relapse is generally made in sex-mismatched cases and based on the finding of the donor sex chromosomes in the leukemia cells. When multiple genetic assays for chimerism are applied, both donor and host markers are present in some cases, making interpretation complex [15]. The mechanism of leukemogenesis in donor cells is unknown; it could include recapitulation of the original leukemogenic process in donor cells, transfer of genes or chromosomes from recipient leukemia to donor cells, or the effect of a leukemic microenvironment. One interesting case was reported in which the patient and the donor shared a germline CEBPA mutation. Donor hematopoietic cells evolved into overt acute myeloid leukemia (AML) by developing a second CEBPA mutation in the recipient bone marrow microenvironment. These were identical with the acquired mutations identified in the patient's original leukemia [16].

Relapse may occur by immune escape from GVL effects. This may be due to loss of expression of leukemia-related antigens [17]; one case was reported associated with loss of expression of a human leukocyte antigen (HLA) haplotype by deletion of chromosome 6 [18]. Another mechanism of immune escape is development of tolerance in donor-derived T cells post-transplant. Antigen-specific T cells may be deleted over time, which has been associated with relapse post-transplant [19]; such patients could potentially be treated by donor lymphocyte infusion (DLI) or second transplants, administering non-tolerized donor T cells.

Chronic myeloid leukemia

Relapse post-transplant has been most extensively studied in patients with chronic myeloid leukemia. Prior to the advent of tyrosine kinase inhibitors, allogeneic hematopoietic transplantation was commonly employed as primary treatment of this malignancy. DLIs were initially studied in this disease [20]. Over 70% of patients with minimal residual disease (MRD) or relapsing into a chronic phase achieve a durable complete remission [21]. Patients who had relapsed to accelerated or blastic phase disease had a lower probability of achieving remission (33 and 16%, respectively [22]). The major complications are GVHD and myelosuppression [23]. GVHD is more common with higher T-cell doses, short intervals from transplant to DLI, and use of unrelated donors. With matched sibling donors, initial infusion of a relatively low cell dose (≤10^7 T cells/kg) with subsequent escalating doses if needed produces a lower rate of GVHD than higher cell doses and has the same ultimate efficacy of achieving remission [24–26]. Tyrosine kinase inhibitors can induce complete remission in patients who relapse post-transplant, in patients who are not resistant to these agents [27]. The leukemia generally recurs if the tyrosine kinase inhibitor is discontinued. Promising results have been reported for patients

with tyrosine kinase-resistant chronic myelogenous leukemia (CML) using a reduced-intensity conditioning regimen and DLI if there was residual disease present post-transplant [28,29].

Acute myeloid leukemia and myelodysplastic syndrome (MDS)

Allogeneic hematopoietic transplantation is a major treatment for AML/MDS. Relapse is the major cause of treatment failure and extensive research has been conducted to evaluate approaches to prevent or treat relapse post-transplant.

Disease recurrence is a devastating event after allogeneic hematopoietic stem-cell transplantation for AML or advanced MDS. The median time to relapse is approximately 4 months and the majority of relapses occur within 2 years after transplant. The prognosis is usually poor [30,31]. Overall 5-year survival of all patients relapsing post-transplant for AML or MDS at our center is 6%. However, many patients can respond to further treatment and a substantial minority can still achieve a durable remission, usually after a second allogeneic transplant or donor lymphocyte infusion [32].

A number of patient-, disease-, and treatment related factors identify patients at highest risk for relapse post-transplant, summarized in Table 70.1. The major disease-related factors predicting for relapse include disease status (active disease vs. remission), cytogenetics, and high-risk molecular abnormalities, particularly the FLT3-ITD mutation [33]. The cytogenetic abnormalities associated with relapse post-transplant differ from those reported with standard chemotherapy. Only the presence of complex cytogenetics with four or more abnormalities was predictive of relapse in a large Center for International Blood and Marrow Transplant Research (CIBMTR) registry analysis [34]. Intriguingly, the occurrence of cytomegalovirus or other herpesvirus infections is associated with a reduced risk of leukemia relapse [35]; the mechanism of this benefit is unknown, but is likely related to immune activation.

Donor factors may affect the risk of leukemia relapse. The use of donors with predicted natural killer (NK) cell alloreactivity [36,37] or expressing certain activating killer immunoglobulin-like receptor (KIR) genes or KIR haplotypes related to NK cell reactivity is associated with a reduced risk of relapse [38–40].

Non-myeloablative and reduced-intensity preparative regimens are commonly used to allow treatment of older and medically infirm patients who might not be able to tolerate myeloablative regimens [41]. Few randomized studies have been performed [42], but this approach may be associated with a higher risk of relapse, but counterbalanced by lower treatment-related mortality [43].

Table 70.1 Risk factors for relapse after allogeneic transplantation for AML/MDS

Patient
Older recipient age
Disease
Disease not in first remission
Refractoriness to salvage chemotherapy
Unfavorable cytogenetics
FLT3-ITD mutations
Minimal residual disease detected pre- or post-transplant
Transplant
Gender donor–recipient combinations other than female to male
Specific KIR haplotypes in the donor
Single versus double umbilical cord transplants
Use of non-myeloablative or reduced-intensity preparative regimen
In vivo or in vitro T-cell depletion
Mixed chimerism post transplant in CD34⁺ cells
Occurrence of cytomegalovirus infection

The presence of pre-transplant MRD is associated with an increased risk of leukemia relapse post-transplant. Walter et al. studied a large cohort of adults with AML in first complete remission undergoing myeloablative conditioning [44]. Five-year estimates of overall survival (OS) were 26 and 79% for MRD-positive and -negative patients, respectively, and 2-year estimates of relapse were 58 and 14%, respectively. Although the presence of MRD was closely associated with other adverse risk factors, this approach could identify patients at high risk for relapse.

Chimerism analysis post-transplant has been reported to predict leukemia relapse, but data are conflicting. Loss of donor chimerism or persistent mixed donor–recipient chimerism may precede acute leukemia relapse, but the kinetics of engraftment in different cell populations vary with different preparative regimens [45]. Mixed myeloid chimerism, particularly an increasing proportion of host myeloid cells, has been associated with leukemia relapse [46]. The kinetics of donor–recipient chimerism within CD34⁺ cells may provide information regarding leukemia recurrence [46–48]. Mixed lymphocyte chimerism is common with the commonly used busulfan–fludarabine preparative regimen. Mixed lymphoid chimerism alone has not predicted for relapse in our experience [49].

Relapse of AML or MDS is classically diagnosed by morphologic criteria. Morphologic diagnosis of relapsed MDS post-transplant can be challenging. Patients may have cytopenias for many reasons and dysplastic features are often present in patients in remission post-transplant; a morphologic diagnosis of MDS may mistakenly be made. If the disease-related clonal cytogenetic abnormality is present in recipient-derived cells, this definitively demonstrates persistent or recurrent disease. Chimerism studies are useful; if the recipient has 100% donor myeloid cells, overt relapse of the recipient MDS cannot be present. Patients with AML in morphologic remission who have residual cytogenetic abnormalities or aberrant phenotype by flow cytometry have residual disease and a poor prognosis [50].

The definition of relapse is evolving due to the development of increasingly sensitive methods for the identification of MRD [51–57]. Real time quantitative polymerase chain reaction-based molecular techniques have the highest sensitivity, but their use is limited to patients with a molecular marker of their disease. This approach can detect MRD, identifying leukemia-related translocations [58], NPM1 [55,59], and FLT3 internal tandem duplication (ITD) [60]. Overexpression of the non-mutated Wilms tumor gene 1 (*WT1*) is found in 80–100% of AML cases, and has been found to predict relapse [61–63].

Patients relapsing post-allogeneic hematopoietic transplantation have a poor prognosis. Duration of remission after hematopoietic stem-cell transplantation is an important predictor of survival after recurrence; the best results occur in patients with remission duration longer than 6 months. Figure 70.1 shows the survival of patients with a time from transplant to relapse less than or greater than 6 months. One-year survival was 8% versus 30%. Adverse prognostic factors include receiving the initial transplant while in relapse, having poor cytogenetic and molecular markers, and receiving transplants from alternative donors [2,3,64].

Recipient age, performance status, comorbidities, and presence of active GVHD are important factors in choosing salvage treatments [65]. Indolent relapses are more amenable to intervention than rapidly proliferating leukemias. Patient preference is an important consideration; transplant recipients have already gone through prolonged active treatment, often at a remote transplant center; some patients are inclined to continue aggressive therapy,

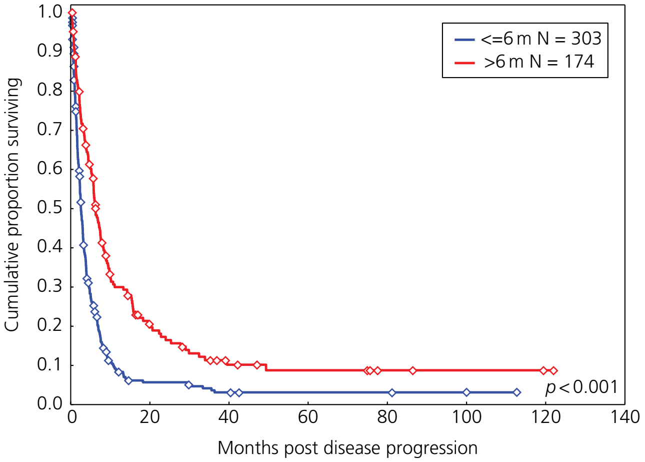

Figure 70.1 Survival of AML/MDS patients relapsing following allogeneic hematopoietic transplants at the M.D. Anderson Cancer Center since 2000. Those relapsing less than 6 months post-transplant (dark curve) have a particularly poor prognosis.

whereas others realistically prefer to return to their homes and receive palliative care.

Selection bias affects the outcomes in all series reporting results of treatment of relapse post-transplant. A minority of patients are enrolled in clinical trials, and an even smaller group achieve remission and long-term survival [30,65–67]. The choice of salvage treatments reflects institutional experience and varies widely. Several approaches have been used, including immunosuppression withdrawal, salvage chemotherapy, DLI, second allogeneic hematopoietic transplants, and combinations of these modalities [68].

Despite anecdotal reports of success, immunosuppression withdrawal is unlikely to induce clinical benefit in patients with AML/MDS with morphologic relapse [66] and should not delay more effective interventions. GVHD often complicates early or rapid withdrawal of immunosuppressive therapy, and may jeopardize the success of subsequent treatment. The worst situation is to have relapse and acute GVHD. We recommend continuing immunosuppressive therapy in patients who have active GVHD and a slow taper of immunosuppressive treatment in others.

Results of conventional chemotherapy remain poor in patients relapsing post-hematopoietic transplantation and the reported complete remission (CR) rates (0–60%) are highly influenced by remission duration and patient selection [69]. Patients may respond to salvage chemotherapy, particularly if they had chemosensitive disease before the initial transplant. In that case, retreatment with anthracycline- and cytarabine-based regimens may be effective.

Patients with FLT3-ITD mutations may respond to treatment with an FLT3 tyrosine kinase inhibitor. Sorafenib produced a prolonged remission in two of four relapsed FLT3-ITD-positive AML patients after allogeneic hematopoietic cell transplantation [70]. We were unfortunately unable to replicate sorafenib treatment results, and had no CR in 16 patients [71]. Other FLT3 tyrosine kinase inhibitors are under study. Patients tend to relapse quickly when the tyrosine kinase inhibitor is stopped, but these agents may induce transient responses that can be a bridge to a second allogeneic transplant.

5-Azacytidine has been used for the treatment of patients with MRD or overt relapse post-transplant. It is a DNA hypomethylating agent that can induce leukemic cell differentiation and may also increase the “immunogenicity” of tumor cells [72,73], augmenting GVL activity [74]. We evaluated the feasibility and possible efficacy of using low-dose 5-azacitidine (doses ranging from 16 to 40 mg/m^2) to treat and/or prevent disease recurrence after allogeneic hematopoietic cell transplantation in AML patients; five of nine patients with recurrent disease responded [75]. Lübbert et al. [76] administered 5-azacitidine followed by DLI to treat 26 patients with AML relapsing after allogeneic hematopoietic transplantation, and observed acceptable toxicity with prolongation of survival among responders. Bolaños-Meade et al. [77] reported 10 patients with myeloid malignancies (mostly AML) who received azacitidine for relapse post-allogeneic hematopoietic transplantation; six patients achieved CR and five remained disease free at a median follow-up of 624 days. Platzbecker et al. reported azacitidine (75 mg/m^2) to treat MRD based on a decreasing CD34-donor chimerism post-transplant [78]. Among 19 evaluable patients, 53% had complete clearance of MRD, defined as an increase in CD34-donor chimerism. These data led to consideration of this agent for post-transplant maintenance treatment, given with the goal of preventing relapse.

Chemotherapy alone generally produces only short-term responses in AML/MDS patients relapsing post-transplant and the best results have been achieved when a DLI or a second allogeneic transplant is performed to consolidate a chemotherapy-induced response. DLIs are frequently given to augment GVL effects as treatment of relapse post-transplant [79]. Although highly effective for the treatment of CML, AML has only intermediate sensitivity to GVL effects. DLIs are generally ineffective for relapsed disease when given alone, although there are some long-term survivors when given following salvage chemotherapy [65]. Results are very dependent on patient selection. DLIs may be complicated by GVHD, infection, and pancytopenia. Most responses do not translate into long-term survival [80]. Schmid et al. reviewed 399 patients with AML relapsing post-transplant. Estimated survival at 2 years was 21% for patients receiving DLI and 9% for those not receiving DLI. Better outcomes were associated with age <37 years, relapse occurring more than 5 months post-transplant, and use of DLI. A lower tumor burden at relapse, female gender, favorable cytogenetics, and being in remission at time of DLI were predictive for survival in a multivariate analysis. Two-year survival was 56% if DLI was performed in remission or with favorable karyotype, and 15% if DLI was given in aplasia or with active disease [65]. Levine et al. reported 57 patients with relapsed advanced myeloid malignancies receiving cytarabine-based chemotherapy and granulocyte colony-stimulating factor (G-CSF)-mobilized DLI; 27 patients experienced CR. GVHD was observed in 56% of the patients. Treatment-related mortality was 23%. The OS at 2 years for the entire cohort was 19% [81]. There is a higher rate of DLI-induced GVHD with unrelated or mismatched donors compared with matched siblings [82]. There are no randomized comparative trials to support the use of DLI versus chemotherapy alone or second allogeneic transplants [65,81,83].

A number of strategies have been studied to improve the efficacy and reduce DLI-induced GVHD. Adoptive transfer of ex vivo-selected T cells recognizing minor histocompatibility antigens (mHAs) may avoid the risk of GVHD while mediating an antileukemia effect [84,85]. Warren et al. reported the results of a phase I clinical trial in which the safety of adoptively transferring donor-derived $CD8^+$ cytotoxic T cells (CTCs) was evaluated. T-cell clones recognizing mHAs expressed by recipient hematopoietic cells but not by recipient dermal fibroblasts were given to patients with recurring AML after myeloablative allogeneic hematopoietic transplantation [86]. Generating therapeutic doses of T cells was complex but feasible. Unfortunately, GVHD with pulmonary toxicity was seen in three of seven patients, and the authors were also unable to show sustained in vivo persistence of transferred $CD8^+$ T cells. Next-generation sequencing may be able to identify unique targets for immunotherapy for each donor–recipient pair [87].

Second hematopoietic transplants can induce durable CR in a fraction of AML/MDS patients with relapse post-transplant. Registry data and single-center retrospective analyses show that the likelihood of success with a second transplant is increased by achievement of a morphologic CR (or minimal disease state) prior to the second transplant, and also by a CR duration longer than 6 months after the first allogeneic transplant; 20–30% of patients can achieve long-term survival in this setting [66,88–92]. We believe that this is the most effective treatment for patients in good general medical condition with chemosensitive relapse and should be considered the standard of care for these selected patients. Figure 70.2 shows progression-free survival of AML/MDS patients relapsing post-transplant at the M.D. Anderson Cancer Center who received second hematopoietic transplants. Patients who had achieved CR or CR with incomplete hematopoietic recovery after salvage chemotherapy had 21% long-term survival. Selected patients with low bulk residual disease post-salvage chemotherapy or untreated early relapse may also benefit; 16% of these patients survived disease free for over 5 years. Patients with overt relapse or chemoresistant disease are not good candidates for second transplants and should be offered supportive care or considered for clinical trials of novel therapeutic approaches.

There is no consensus regarding the optimal preparative regimen for a second allogeneic transplant; myeloablative and reduced-intensity regimens have been used. Myeloablative regimens produce lower relapse rates, but treatment-related mortality is higher than with reduced-intensity conditioning [90]. Most centers use a different regimen to that with the initial transplant and reduced-intensity regimens have generally been used in older patients. At our center, if a busulfan-based regimen was used for the initial preparative regimen, we generally employ a reduced-intensity melphalan and fludarabine regimen for the second transplant in adults. For young, fit patients, a high-dose total body irradiation-based regimen may be considered.

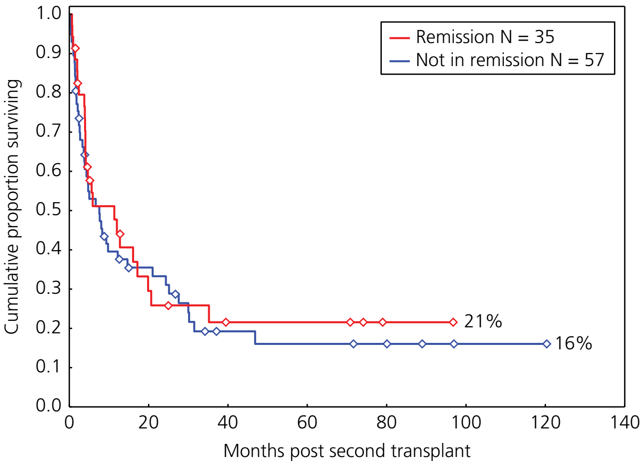

Figure 70.2 Progression-free survival for patients receiving second allogeneic hematopoietic transplants who had achieved a remission with salvage chemotherapy (light curve), or who had low bulk disease but were not in remission (dark curve).

Donor availability is a major issue after unrelated donors or umbilical cord blood (UCB) transplants. A second transplant from the same donor is not an option for UCB recipients. There has been speculation that the use of a different donor or cell source may improve the outcome of a second transplant. A different donor would likely express different minor histocompatibility antigens and might produce a potentially more effective GVL effect. A recent study by Christopeit et al. reported that there was no benefit in using a different donor for a second transplant, and the use of related donors had better outcomes than with unrelated donors [93]. An alternative strategy would be to perform an HLA non-identical cord blood or haploidentical transplant with the goal of potentially inducing a more potent immunologic effect. Large clinical trials of this approach have not been reported.

The major problem is that most patients with relapse post-transplant will not achieve even a transient remission with salvage chemotherapy. One approach is to administer intensive myelosuppressive therapy to cytoreduce the leukemia and achieve a hypoplastic bone marrow., The patient could then receive a reduced-intensity allogeneic transplant at the nadir of their blood counts before the leukemia could regenerate. This approach has been effective in some studies for initial transplants in patients with relapsed AML [94], but has not been specifically studied in patients with relapse post-transplant.

Acute lymphoblastic leukemia

Of all the major leukemias, acute lymphoblastic leukemia (ALL) appears least affected by GVL effects [6,95]. Detection of MRD before or after transplantation identifies patients at higher risk for relapse [96]. The European Bone Marrow Transplantation Group recently reported that median survival of less than 6 months' prognosis is related to advanced disease at initial transplant, time to relapse post-transplant, and percentage blasts in the peripheral blood [97]. DLIs have generally been ineffective; the CIBMTR analyzed 44 patients receiving DLI. Two of 15 patients receiving no other treatment achieved CR and the OS was 13% at 3 years [98]. Novel cell therapy approaches, such as the use of redirected T cells reactive against CD19 by a genetically modified chimeric antigen receptor, are under investigation [99]. Second allogeneic transplants have been performed in selected patients, who usually achieved a subsequent remission. Approximately 20–25% achieved durable remissions [90,100].

Lymphoid malignancies

There has been limited experience with the treatment of relapse post-transplant in patients with lymphomas, Hodgkin disease, chronic lymphocytic leukemia (CLL), and multiple myeloma.

Allogeneic transplants have produced a high rate of durable remission in follicular lymphoma and mantle cell lymphoma. Several groups have reported responses in selected patients relapsing after T-cell replete allogeneic transplants. Relapse has been more frequent in patients receiving alemtuzumab-based regimens [101]. There was a low rate of treatment-related mortality, but a high risk of relapse; DLIs were effective in achieving durable CR in over 50% of patients with follicular lymphoma or mantle cell lymphoma. It was reported that 19 of 24 patients with relapse after this regimen achieved a complete remission and 64% were disease free at 4 years post-transplant [102,103]. There were poor results with DLI for the treatment of aggressive lymphomas [101].

Allogeneic transplantation with non-myeloablative or reduced-intensity conditioning is frequently used for patients with advanced CLL [104]. Relapse or persistent disease is a common problem, particularly after an alemtuzumab-containing preparative regimen [105]. Khouri et al. reported that 20 of 43 patients had durable responses to immune manipulation including immunosuppression withdrawal, rituximab treatment, or DLI [106]. Several patients had durable remissions after rituximab treatment alone, suggesting augmentation of GVL effects. Cell therapy using anti-CD19 chimeric antigen receptor T cells are promising against a broad range of lymphoid malignancies and chronic lymphocytic leukemia [107].

Allogeneic hematopoietic transplantation is frequently performed for Hodgkin disease that has recurred following autologous hematopoietic transplantation. Selected patients with recurrent disease responded to DLI [108,109]; Anderlini et al. reported response in four of nine patients [109]. There is recent interest in combining DLI with brentuximab vedotin [110].

Multiple myeloma

Allogeneic hematopoietic transplantation has been studied in patients with multiple myeloma. There remains a high risk of relapse, but a fraction of patients may achieve a durable CR. A graft-versus-myeloma effect of allogeneic hematopoietic transplantation exists against multiple myeloma [111]. DLIs can produce CRs [112]. Most responders also developed GVHD [113]. Beitinjaneh et al. reported on 23 patients with multiple myeloma who received DLI after allogeneic hematopoietic transplantation. Eight patients received preemptive DLI for residual disease and 15 received DLI for the treatment of recurrent or progressive disease. Five patients (22%) achieved a complete or a very good partial response, and eight patients (34%) had stable disease after the DLI. Patients who received DLI for residual disease had a higher response rate than those treated for disease progression (50% vs. 7%) and a longer median survival (28.3 vs. 7.6 months) [114].

Prevention of relapse

There is major interest in potential interventions that could be performed post-transplant to reduce the risk of recurrent malignancy post-transplant. The approaches under study include maintenance treatment with chemotherapy, hypomethylating agents, immunomodulatory therapies, vaccines, and cellular therapies. These approaches have been most extensively studied in patients with AML.

Interventions could be applied to patients considered at high risk for relapse or in patients with detection of MRD. Hematologic relapse is often preceded by a period with detectable MRD. A preemptive strategy to monitor and treat low bulk disease may improve outcomes compared with waiting for overt relapse to occur, while avoiding exposure of cured patients to treatment-related toxicities.

Prevention is more accurately treatment to eradicate occult residual malignancy after transplant. A proposed intervention must not jeopardize the graft or hematologic/immune reconstitution and have acceptable toxicity. Interventions to prevent relapse have to be implemented early, especially for patients who were not transplanted in CR, given that the median time to relapse post-transplant is only 4 months.

As indicated, azacitidine has direct antileukemia effects and may favorably enhance GVL effects against myeloid malignancies. Azacitidine treatment also causes expansion of T-regulatory cells and inhibits he development of GVHD [115], making it attractive as post-transplant therapy. We conducted a phase I study in 42 relapsed or refractory AML patients who underwent reduced-intensity allogeneic hematopoietic transplantation. The maximum tolerated dose was defined at 32 mg/m^2/day for five consecutive days every 4 weeks for at least four cycles, starting on the sixth week after transplant. The dose-limiting toxicity was thrombocytopenia. We are now performing a prospective randomized trial of high-risk AML/MDS patients who are in remission and medically stable at 1 month post-transplant. Patients are randomized to receive monthly courses of azacitidine for 1 year versus no maintenance therapy (ClinicalTrials.gov identifier: NCT00887068).

As indicated, patients with FLT3-ITD mutations are at high risk for relapse after allogeneic hematopoietic transplantation. A number of novel FLT3 tyrosine kinase inhibitors are being studied for the prevention of relapse in the post-transplant setting [116,117]. No data regarding their tolerability and efficacy are available at present. These trials will need to be attentive to toxicities, including myelosuppression and potential drug interactions [118,119].

Early immunosuppression withdrawal, with or without prophylactic DLI, has been employed with variable results [120]. T cells are mediators of GVL effects. In vivo T-cell depletion with anti-T-cell antibodies has been reported to increase the risk of relapse post-transplant, particularly following reduced-intensity conditioning [10]. One approach to separate GVL from GVHD is to perform an initial T-cell-depleted transplant with in vivo or in vitro T-cell depletion to achieve engraftment without GVHD. A planned prophylactic DLI can be administered approximately 6 weeks later to augment GVL effects. This approach is under study. As discussed above, DLI may be complicated by GVHD, and the efficacy of this approach to prevent relapse has not been investigated in randomized trials [60]. This platform of delayed DLI does allow the evaluation of engineered T-cell infusions to target specifically the leukemia or reduce GVHD. Antigen-specific T cells targeting the malignant cells can be infused. T cells can also be transduced to express herpesvirus thymidine kinase [121] or a modified caspase-9 [122], which can act as a suicide switch; the genetically modified T cells can be eliminated by administration of an otherwise non-toxic activating drug if GVHD or other toxicity occurs [123].

Peptide vaccines may improve the GVL effect with little toxicity. Specific cytolytic T-cell responses may be induced to leukemia-associated antigens that are over- or aberrantly expressed by malignant cells, such as the PR1 peptide in AML [124,125]. Numerous reports have documented disease remissions following the use of peptide vaccines, but controlled trials have not been completed and widespread use of this strategy is not yet available [126,127]. Molldrem et al. are investigating the PR1 peptide both as a myeloid leukemia-associated antigen capable of generating clinically relevant immune responses [19], and also as a potential target of a therapeutic monoclonal antibody [128]. Rezvani et al. [126] conducted a clinical trial investigating HLA-A0201-WT1 peptide vaccine administered in conjunction with PR1 vaccine to leukemia patients and observed an increase in functional WT1-CTLs following vaccination in five of eight patients. Disease regression, as measured by WT1 expression, was correlated with an increase in anti-WT1 and PR-1 cytolytic T cells. Another potential strategy uses donor PR1 peptide vaccination prior to stem-cell harvest, in an attempt to enhance the GVL effect.

Donor-derived NK cells mediate antitumor effects against a broad range of hematologic malignancies and do not appear directly to cause GVHD [129]. Predicted NK cell alloreactivity is associated with a reduced risk of relapse in AML patients following haploidentical transplants [37]. The risk of AML relapse post-transplant was decreased for recipients from related and unrelated donors with group B KIR haplotype [39,130,131]. Adoptive therapy with NK cells can induce remission in patients with advanced AML [132] and has been used to prevent relapse post-chemotherapy [133].

A limitation is the relatively small cell dose possible that can be collected from normal donors by apheresis. We and other investigators are studying ex vivo expansion of NK cells [134] for infusion with allogeneic hematopoietic transplantation.

Conclusions and future directions

Relapse remains the major cause of treatment failure after allogeneic hematopoietic transplantation as treatment for malignancy. Immunomanipulation and donor lymphocyte infusions are effective in many patients with CML and indolent lymphoid malignancies. The occurrence of overt relapse post-transplant has a grim prognosis in acute leukemias, but selected patients may respond to further chemotherapy and a fraction can achieve durable CR with a second hematopoietic transplant or DLI. There is considerable interest in maintenance strategies or preemptive therapy using targeted chemotherapy, immunomodulatory treatments, or antigen-specific immunotherapy. Prospective clinical trials are in progress to evaluate each of these modalities.

CHAPTER 71

Hematopoietic Cell Transplantation for Thalassemia

Guido Lucarelli and Javid Gaziev
International Centre for Transplantation in Thalassemia and Sickle Cell Anemia, Mediterranean Institute of Hematology, Rome, Italy

Introduction

The thalassemias refer to a diverse group of hemoglobin disorders characterized by a reduced synthesis of one or more of the globin chains (α, β, γ, δβ, γδβ, δ, and εγδβ) and are the most common monogenic disorders to cause a major public health problem in the world [1]. Globally it is estimated that there are 270 million carriers of hemoglobin disorders, of which 80 million are carriers of β thalassemia. Currently recommended medical therapy of thalassemia consists of lifelong regular blood transfusions to maintain hemoglobin levels between 9 and 10 g/dL together with chelation therapy aimed at reducing iron accumulation as a consequence of chronic transfusions. Desferrioxamine (DFO), the first available chelator, administered as continuous subcutaneous infusion for at least 8–12 h daily has improved life expectancy up to and beyond the second decade of life, and has dramatically improved the quality of life for children with thalassemia. Recently introduced in clinical practice the once-daily oral chelator deferasirox has been shown to remove iron from the liver and the heart with improved compliance, although its efficacy compared to desferrioxamine in the long term has not yet been determined. However, in many countries where the transfusion and the iron chelation treatment is given irregularly, mainly due to the high cost, the majority of patients with homozygous β thalassemia die in childhood, from chronic anemia and its complications and from the organ iron overload.

Hematopoietic cell transplantation (HCT) has been used in attempts at curing thalassemia. The first successful marrow transplant for thalassemia was reported in 1982 by Thomas and his colleagues [2], and the first reports of series of transplants were by Lucarelli et al. [3–5]. Some discussion of the epidemiology, molecular biology, pathophysiology, clinical features, and supportive therapy is necessary in an attempt to define how, when, and for whom to pursue bone marrow transplantation (BMT) for thalassemia.

Epidemiology and etiology

Even though the relationship has not been proven conclusively for β thalassemia, the geographical distribution coincides historically with malarial areas and there is more convincing evidence for β thalassemia and sickle-cell disease. Because of a selective advantage of heterozygotes against the severe form of malaria, the frequencies of β thalassemia are particularly high in the malarial tropical and subtropical regions of the Mediterranean area, the Indian subcontinent, Africa, and Southeast Asia [1]. The prevalence of β-thalassemia carriers is low in people of Northern European origin (1:1000), while in the Northern Mediterranean countries the carrier prevalence varies between 1% and 19%. In the Middle East countries carriers are around 3%, while in central Asia the prevalence is 4–10%. In the Indian subcontinent and Southeast Asia, β thalassemia coexists with hemoglobin E (HbE) in carrier rates that range from 1–40% [6]. Worldwide about 60,000 children with a major thalassemia and 250,000 with a sickle cell disorder are born annually, giving a rate of more than 2.4 affected children per 1000 births [7]. The epidemiology of the disease is changing due to recent population migrations. In Europe, the United States, and Australasia, thalassemia has become an important part of clinical practice.

Molecular and clinical biology

More than 200 mutations affecting the β-globin gene are known to result in a phenotype of β thalassemia. With the exception of the 619 bp deletion, which accounts for 20% of the β thalassemias in Asian Indians [8], the common mutations of β thalassemias are caused by point mutations as single-base substitutions, minor insertions or deletions of a few bases within the gene or its immediate flanking sequences and are classified according to the mechanism by which they affect gene regulation: transcription, RNA processing, or RNA translation [9]. These genetic defects lead to a variable reduction in β-globin production ranging from a minimal deficit (β^+ thalassemia) to complete absence (β^0 thalassemia).

The pathophysiology of β thalassemia relates to a quantifiable deficiency of functional β globin, which leads to an imbalanced globin chain production and an excess of α-globin chains [1,10]. The latter are not able to form viable tetramers and instead precipitate in the red cell precursors forming inclusion bodies that cause mechanical damage and the premature destruction of red cell precursors in the bone marrow leading to ineffective erythropoiesis. The red cells that survive to reach the peripheral circulation are prematurely destroyed in the spleen, which becomes enlarged, eventually leading to hypersplenism. Thus, anemia in β thalassemia results from a combination of ineffective erythropoiesis, peripheral hemolysis, and an overall reduction in hemoglobin synthesis leading to intense proliferation and expansion of the bone marrow with the resulting skeletal deformities. These secondary complications of bone disease,

splenomegaly, endocrine and cardiac damage can be related to the severity of anemia and the iron loading that results from increased gastrointestinal iron absorption and blood transfusions.

Clinical features

The clinical manifestations of β thalassemia are extremely diverse, ranging from the transfusion-dependent state of thalassemia major to the slightly less severe transfusion-dependent state of thalassemia intermedia or to the asymptomatic state of thalassemia trait. β thalassemia is usually inherited in an autosomal recessive manner, although a few dominantly inherited forms can also occur. The most severe form of disease is characterized by the complete absence of β-globin production and results from the inheritance of two β^0-thalassemia alleles, homozygous or compound heterozygous states. These combinations usually result in β-thalassemia major and the patients present within 6 months of life with severe anemia, and if not treated with regular blood transfusions, die within the first 2 years. The red cells are microcytic with marked anisochromasia. The bone marrow shows marked erythroid hyperplasia, and the serum ferritin level is elevated. The hemoglobin pattern of patients with β-thalassemia major consists of a variable increase in HbF, which can account for 8% to 90% of the total hemoglobin concentration and show a variable quantity of HbA_2 up to 6% [1]. In children and young adults the expansion of hyperplastic bone marrow results in skeletal deformities and bone disease. Because of chronic anemia and iron overload, endocrinopathies (such as hypopituitarism, hypothyroidism, hypoparathyroidism, diabetes mellitus), cardiomiopathy, and testicular and ovarian failure become common as the child with thalassemia grows older [1,11]. Chronic lung disease and pulmonary hypertension are other complications that are being increasingly recognized in older β-thalassemic patients, and are thought to be related to the increased tendency for thrombosis and small pulmonary emboli [12].

Non-transplant approaches

The current conventional treatment of β-thalassemia major consists of lifelong regular blood transfusions combined with daily available chelation therapy. In 1964, Wolman reported that patients maintained at a higher baseline hemoglobin level had less severe complications and were in better health than those maintained at lower hemoglobin levels [13]. Stimulated by this observation, Piomelli and his colleagues studied a transfusion regimen designed to prevent the baseline hemoglobin from falling below 10 g/dL. When this hypertransfusion regimen was instituted in infancy and rigorously implemented, cardiomegaly and bone malformation were greatly reduced, although normalization of growth was not achieved and the development of hypersplenism was not prevented [14]. The target hemoglobin level of 10 g/dL was designed to depress endogenous erythropoiesis and thereby avoid marrow hypertrophy with accompanying marrow space extension. This objective was partially achieved, but complete suppression of endogenous red cell production requires that hemoglobin be maintained at levels greater than 13 g/dL. There are major obstacles in the way of achieving such levels. Raising the baseline hemoglobin level from 10 g/dL to 11 g/dL requires a 20% increase in the red cell transfusion requirement [15], and there are many reasons for minimizing transfusion in patients with thalassemia.

Hypertransfusion regimens have a major impact on iron traffic and distribution in patients with severe hemolytic anemia. The complications of iron overload such as endocrine deficiency, hepatic and pancreatic damage, and heart disease are the principal causes of morbidity and mortality in patients with thalassemia receiving this form of therapy. The transfusion of 165 mL of packed red cells per kilogram per year is associated with an annual iron intake of approximately 180 mg/kg [15]. More recently, clinical experience suggested that a moderate transfusion regimen by maintaining a hemoglobin level of 9–10 g/dL throughout life may reduce iron loading in patients with β-thalassemia major without producing excessive expansion of erythropoiesis [16].

Iron accumulation resulting from both repeated blood transfusions and increased gastrointestinal absorption in β-thalassemia major patients may cause serious organ damage and ultimately death. Effective removal of this excess iron can improve survival of these patients. Until the last decade DFO was the only effective iron-chelating drug available in patients with β-thalassemia major. DFO has a strong and selective affinity for iron and does not appear to have any major side effects. However, DFO displays poor bioavailability when given orally and has a rapid plasma clearance. Therefore, DFO is efficient only when administered parenterally over several hours in order to keep a constant serum level. Since the maintenance of steady plasma levels of this agent is essential for the effective management of iron traffic, it must be continuously administered either intravenously or subcutaneously using a special pump (overnight 8–12-h infusion for 5–7 nights). Intensive long-term chelation with DFO proved beneficial for a large number of patients, as evidenced by the gradual decrease of their serum ferritin and liver iron with improved survival [17].

There are two common reasons for the failure of chelation therapy with DFO. In emerging countries where thalassemia is a substantial public health problem, the high cost of the drug and of the supplies for its administration make it unavailable for most patients. Despite wide availability of DFO in Western countries, some patients are unable to comply sufficiently with the prescribed treatment because the effective chelation is unpleasant and cumbersome, requiring daily subcutaneous or intravenous administration leading to poor compliance with therapy. It was therefore obvious that an orally administered chelator was a pressing need.

Two oral iron chelators are currently available for clinical use. Deferiprone or L1 (DFP) is a bidentate chelator, which forms a chelator/iron complex excreted mainly in the urine. At a standard dose (75 mg/kg/day, in three doses) iron stores may decrease in some patients, remain stable in others, and increase in still others [18]. DFP is approved in Europe and many other countries, often as a second-line treatment for iron overload. In general, DFP is less effective in removing liver iron, although great individual variations occur. Toxic effects include agranulocytosis, neutropenia, and arthropathy, which demand close monitoring. Studies in patients treated with DFP have shown significant improvement in cardiac magnetic resonance imaging, consistent with a reduction in cardiac iron overload and improved cardiac function, in comparison with DFO, supporting a potential cardioprotective role of DFP [19].

Another oral chelator is now available – deferasirox (ICL670), which is a member of a new class of tridentate iron chelators [20]. It is orally bioavailable with terminal elimination half-life between 8 and 16 hours, allowing for once-daily administration. A recent phase III randomized study comparing deferasirox to deferoxamine in pediatric and adult patients with β-thalassemia major receiving regular blood transfusions showed that at 20–30 mg/kg/day, deferasirox can keep most but not all patients in even or negative iron balance in rough equivalence with moderate doses of deferoxamine.

The most common adverse events included rash, gastrointestinal disturbances, and mild non-progressive increases in serum creatinine [21]. While efficacy and limits of DFO therapy in transfusion-dependent β-thalassemia major patients are well known, long-term data on these two new oral chelators in treating iron overload are not yet available and they should be investigated in large-scale prospective randomized studies.

The beneficial effect of high levels of HbF in β thalassemia and sickle cell anemia has been recognized for many years. Pharmacologically, three classes of agents have been shown to be capable of inducing HbF to therapeutic levels: erythropoietins, short-chain fatty acid derivatives, and chemotherapeutic agents. However, the sustained pharmacologic induction of HbF to therapeutic levels in β thalassemia has been disappointing. Despite addressing the effective erythropoiesis, correction of the anemia has been difficult because of suppression of erythropoiesis by the currently available pharmacologic agents.

Gene therapy for β thalassemia requires gene transfer into HSCs using integrating vectors that direct regulated expression of β globin at therapeutic levels. Unlike oncoretroviral vectors, human immunodeficiency virus-based lentiviral (LV) vectors can transduce non-dividing cells, and were shown to stably transmit the human β-globin gene and a large LCR element, resulting in correction of the mouse thalassemia intermedia phenotype, with variable levels of β-globin expression [22]. A recent study reported successful lentiviral β-globin gene transfer associated with RBC transfusion independence in a patient with thalassemia intermedia in France [23]. However, there was the emergence of a partially dominant clonal cell population raising concerns regarding the safety of lentiviral vectors, particularly with regard to genotoxicity.

Programs for prevention of thalassemia are presently based on prospective carrier screening and prenatal diagnosis. Although traditional prenatal diagnosis of β thalassemia has been highly effective in some countries the fact that affected pregnancies must be terminated to avoid the birth of affected children makes it unacceptable to most persons. Recently developed preimplantation genetic diagnosis (PGD) with in vitro fertilization has already become an alternative to traditional prenatal diagnosis, allowing only unaffected pregnancies and avoiding the risk for pregnancy termination [24]. PGD completed with HLA typing allows selection of healthy and compatible embryos in families with affected children with the certainty that a source of stem cells will be available for transplantation [24].

Hematopoietic cell transplantation (HCT)

At present, allogeneic HCT is the only rational therapeutic modality for the eradication of β-thalassemia major. It is a form of gene therapy that uses allogeneic stem cells as vectors for genes essential for normal hematopoiesis. Eventually, the vector may well be autologous stem cells transformed by the insertion of normal genes but there is no indication that this approach will be a clinical option in the foreseeable future. All of the transplant procedures in Pesaro discussed in this chapter were performed with bone marrow and the term "bone marrow transplantation" (BMT) is used for these procedures.

There are no controlled trials of HCT versus medical treatment for thalassemia major and few studies comparing quality of life. Regular blood transfusion and iron chelation have improved both survival and quality of life of patients with thalassemia and have changed a previously fatal disease with early death to a chronic, although progressive, disease compatible with prolonged survival [7,25]. Despite the prolonged life expectancy, a recent study from the UK Thalassaemia Register showed a steady decline in survival starting from the second decade, with fewer than 50% of patients remaining alive beyond 35 years mainly because of poor compliance with chelation therapy [26]. In the developing world where thalassemia is more common, most children die before the age of 20 years because of the unavailability of safe blood products and/or expensive iron-chelating drugs. Two recently developed oral iron chelators could allow better compliance with chelation, and therefore could have a favorable impact on survival of patients with thalassemia. However, even an ideal iron chelator with rigorous adherence only substantially reduces, but does not eliminate, the iron overload of patients on lifelong transfusions. The acute toxicities of transplantation are challenged by the observation that in the developed world patients with thalassemia are well served by medical treatment, and in some countries patients receiving regular blood transfusion and chelation could have a better survival rate [17,27]. Unfortunately, these same patients with increasing age currently experience poor outcome on conventional treatment, even in well-resourced countries with universal access to good medical treatment [11,26].

The first two transplant procedures for the treatment of thalassemia with marrow from matched related donors were performed in December 1981, in Seattle, WA, and in Pesaro, Italy. The Seattle approach was based on the assumption that the risks associated with BMT would be increased by the iron overload and by sensitization to human leukocyte antigens (HLAs) induced by hypertransfusion. Therefore, it was decided that early clinical studies would be conducted in very young patients who had received very few transfusions. On December 3, 1981 a 14-month-old child with β-thalassemia major who had been transfused with a total of 250 mL of packed RBCs received BMT from his HLA-identical sister following conditioning with a single dose of IV demethylbusulfan (5 mg/kg) and cyclophosphamide (200 mg/kg, total dose) in Seattle [2]. The treatment was completely successful.

The Pesaro approach was based on an assessment that restricting transplants to untransfused patients was impracticable. On December 17, 1981 the Pesaro team performed a transplant in a 14-year-old thalassemic patient who had received 150 RBC transfusions, using marrow from his HLA-identical brother [3]. This patient rejected the graft and was the first of an extensive series of transplants for thalassemia that provides most of the data supporting this chapter.

Preparatory regimens

To eradicate disordered marrow and achieve engraftment preparatory regimens have generally included total body irradiation (TBI) in association with high-dose chemotherapy. However, the late effects of TBI are well established and may include growth impairment, cataracts, hypothyroidism, and secondary malignancies [28,29], although the risk of these toxicities has not yet been fully explored for cytotoxic regimens that do not involve TBI. These hazards are particularly objectionable in very young patients with potential for a long life span. Busulfan (BU) is an alternative to TBI [30–33]. BU is an alkylating agent with exquisite specificity for the most primitive precursors of the myeloid–erythroid axis. It has been used in low doses for more than 30 years for the treatment of patients with chronic myeloid leukemia, and its toxicity and effectiveness have been well documented in that setting. Studies in rodents demonstrated that marrow-lethal doses of BU have minor toxicity to the lymphoid system and cause little immunosuppression [34]. Canine studies of transplants between dog leukocyte antigen (DLA) identical littermates demonstrated 50% engraftment after BU alone and 95% engraftment when antithymocyte serum was added to the conditioning regimen [35]. Santos et al. reported the first clinical trials of very high-dose BU in the context of BMT [30]. In these studies, patients with acute myeloid leukemia (AML) received allogeneic marrow transplants after immunosuppression with CY (200 mg/kg over 4 days), and oral BU (16 mg/kg over 4 days) was administered as additional antitumor therapy. Early results with this therapy were encouraging, and in successful attempts to reduce early transplant-related toxicity, Tutschka et al. reduced the CY dose to 120 mg/kg over 2 days [36]. To optimize BU treatment, therapeutic drug monitoring (TDM) of oral BU with dose adjustment is widely practiced but with variable results due to the unreliability of oral BU pharmacokinetic assessment because of erratic intestinal absorption and possible dose loss with emesis. A recently developed IV formulation of BU exhibits less interpatient as well as dose-to-dose variability, leading to more reliable and consistent PK estimations [37]. High BU exposure (area under the concentration versus time curve (AUC) $>1500\,\mu$mol/min) was associated with greater toxicity, whereas low exposure (AUC <900 μmol/min) with graft rejection or relapse [38,39]. Consequently, targeting the therapeutic range of exposure may improve clinical outcomes. We prospectively studied the pharmacokinetics (PK) and clinical outcomes of intravenous busulfan (IV BU) in 71 children with pre-existing liver damage who underwent HCT for thalassemia [40]. IV BU was administered every 6 hours as part of a conditioning regimen with PK-based dose adjustment to target a conservative AUC range (900–1350 μmol/min). We found that the first dose of BU clearance (Cl) was significantly higher than the subsequent daily Cl that remained unchanged in following days. Consequently AUC targeting performance was 59% at the first dose of IV BU. One third of patients required dose escalation based on dose 1 AUC whereas mainly dose reduction was needed in the subsequent days due to a "normalization" of the BU clearance in following days. The fluctuations in drug exposure and doses adjustment followed the pattern of BU Cl. To avoid such large fluctuations in drug exposure and frequent dose readjustments, we suggested targeting the lower range of exposure (900 μmol/min) for the dose adjustment based on dose 1 AUC. This procedure should prevent unexpected high exposures at subsequent doses observed in this patient population. For the subsequent dose adjustment, the target dose is the conventional one (i.e., 1125 μmol/min) because the Cl remained unchanged after dose 1. Busulfan is a highly lipophilic molecule that easily crosses the blood–brain barrier and could cause seizure. Therefore during busulfan treatment antiseizure prophylaxis should be administered.

Further, CY has been a component of most conditioning regimens for transplanting patients with hematologic malignancies. Santos et al. reported on its use in high doses (200 mg/kg over 4 days) as the sole antitumor agent in patients receiving allogeneic transplants for leukemia and demonstrated that it was sufficiently immunosuppressive to permit sustained allogeneic engraftment [41]. Also, CY is most commonly employed for the treatment of lymphoid malignancies and solid tumors, and it has been used as a component of combination chemotherapy for the treatment of acute leukemia. It is not considered a highly effective agent against myeloid malignancies, although single-drug studies are not available in this context. The dose-limiting toxicity of CY is to the heart and not to the marrow. Mice, monkeys, and humans recover hematopoiesis promptly after the highest doses of CY because CY does not eliminate HSCs. Therefore CY alone is not an appropriate conditioning modality for BMT for the treatment of thalassemia because the thalassemic marrow would recover rapidly. On the other hand, BU is an agent that has a good possibility of eradicating a diseased erythron but when used alone is not likely to be sufficiently immunosuppressive to permit sustained allogeneic engraftment. A combination of BU and CY can eradicate the thalassemia and facilitate sustained allogeneic engraftment.

Many of the hematopoietic manifestations of thalassemia resemble those of hematopoietic malignancy. The disease is characterized by extreme marrow hyperplasia with aggressive extension of a rapidly proliferating erythron into intra- and extra-medullary areas not usually occupied by marrow. This results in major bone remodeling together with marked hepatomegaly and splenomegaly. By analogy with the behavior of malignant tissue, it might be hypothesized that this large mass of rapidly proliferating hematopoietic tissue would be more difficult to eradicate than normal hematopoietic tissue, and more likely to recur after transplantation. Although post-transplant thalassemic recurrence is a problem, it occurs in circumstances that differ from those usually observed with leukemic relapse. The most common presentation of leukemic relapse is return of host-type leukemia in the presence of a persisting immune system of donor origin. In contrast, the recurrence of thalassemia usually occurs in the context of a return of host-type immune and hematologic reconstitution. Thus, this event has aspects of both relapse and rejection and it is customary to speak of this phenomenon as rejection.

Stem cell sources

There are three possible sources of stem cells to use for transplantation: bone marrow, peripheral blood, and cord blood. Which stem cell source is best for transplantation for thalassemia? Bone marrow is the most frequently used stem cell source for patients with thalassemia. Currently the use of peripheral blood has become the preferred source of stem cells in most transplant centers especially for hematologic malignancies. In the last decade cord blood-derived hematopoietic stem cells have become more frequently utilized for allogeneic transplantation. There are some pros and cons to each source. Easy donation, harvesting high stem cell dose and faster hematologic recovery are pros to peripheral blood stem cell transplantation (PBSC). However, the risk of both acute and especially chronic GVHD is somewhat higher with PBSC than with bone marrow transplants.

No need for separate donation, easy procurement, low incidence of acute GVHD despite 1 or 2 antigen mismatches are advantages of cord blood transplantation. Drawbacks of cord blood transplantation include longer time to engraft with associated high risk for infection and bleeding complications, and unavailability of the donor cells in case of engraftment failure of cell therapy.

A recent study from the Eurocord cooperative group analyzed the outcome of 33 patients with class 1 or class 2 thalassemia, and 11 with SCD who received cord blood cells from a sibling following BUCYATG or BUFLU regimen [42]. In 17 patients TT was added to the conditioning regimens. Seven (21%) out of 33 patients with thalassemia experienced graft failure. A low percentage of patients experienced either acute (11%) or chronic (6%) GVHD, which is encouraging. The 2-year estimate of event-free survival was 79%. Although transplanted patients were in class 1 and class 2, the incidence of graft rejection was higher than after an HLA-matched sibling bone marrow transplantation. An increased risk of graft failure after cord blood transplantation, compared with that in patients given BMTs, has previously been reported. The 1 log lower cell dose in cord blood grafts, which is a well-known disadvantage, probably has a negative influence on sustained engraftment in recipients with non-malignant diseases.

More recently results of transplantation in 183 patients with thalassemia receiving either PBSC ($n = 87$) or bone marrow ($n = 96$) have been reported [43]. Patients were given GVHD prophylaxis with CSA ($n = 60$) or CSA + MTX ($n = 123$). The incidence of grade 2–4 acute and extensive chronic GVHD was 74% versus 57% and 49% versus 17% in the PBSC and bone marrow arms, respectively. Taken together these data clearly demonstrate that the use of bone marrow should be the first choice for transplantation for patients with thalassemia.

Engraftment

Most patients undergoing transplantation for the treatment of thalassemia have been transfused repeatedly. Experience with BMT for the treatment of aplastic anemia in heavily transfused patients demonstrated that a history of many pre-transplant transfusions increased the probability of graft rejection [44,45]. There is a substantial incidence of graft rejection in thalassemia patients after most preparatory regimens for marrow grafting, and this seems to be related to the stage of disease at the time of transplant. As discussed earlier, in most cases of graft rejection the thalassemic marrow will regrow and subsequent survival will be long (albeit with thalassemia). Occasionally, patients will reject grafts without recurrence of thalassemia. Unless rescued by a second transplant such patients will die from the consequences of marrow aplasia. The treatment of patients after graft rejection will differ depending on whether the rejection is accompanied by regeneration of host-type hematopoiesis or by marrow aplasia. Our experience with this situation is discussed later.

Transplant-related morbidity and mortality

HCT can be a dangerous undertaking. Regimens capable of eradicating a diseased marrow and facilitating persistent engraftment are necessarily toxic, and the consequences of successful allogeneic marrow engraftment include acute and chronic GVHD, syndromes associated with severe immune incompetence. Both prophylaxis against GVHD and methods for its treatment are immunosuppressive. Transplant-associated toxicity may be aggravated by GVHD and by measures aimed at the prevention of this complication. Such toxicity can be categorized either as regimen-related toxicity (RRT) or as GVHD.

In studies of HCT for the treatment of hematologic malignancies, RRT from the preparative regimens has been well described [46,47]. The lungs and liver are the organs most at risk for toxicity induced by TBI and BU while the heart is the main site of CY-induced damage. Increasing patient age, previous exposure to cytotoxic agents and the presence of latent viruses such as hepatitis C and cytomegalovirus adversely influence these toxicities. Patients transplanted for the treatment of thalassemia derive benefit from the fact they are usually young and without prior exposure to cytotoxic agents. However, because of previous intensive transfusion therapy they will have a high probability of carrying harmful viruses and have organ damage induced by extreme iron overload.

Clinical transplant experience

Experience of the first 20 years (1982–2002)

By far the largest body of experience in the treatment of thalassemia with BMT has been accumulated in Pesaro, Italy. From December 1981 to June 2001, 915 patients with homozygous β thalassemia received marrow transplants. The thalassemia-free survival of the entire group of patients (aged 1 through 35 years at the time of the transplantation) is 69%. For 880 patients, the donors were HLA identical (853 siblings, 27 parents), 29 were HLA partially matched relatives, and six were HLA-identical unrelated donors. Most patients were treated with one of two types of regimens: one, used for 547 patients, prescribed BU 14 mg/kg and CY 200 mg/kg and the other used BU with a lower dose of CY for patients believed to be especially susceptible to the toxic complications associated with this high dose of CY.

In early experience, the best results were obtained in younger patients [5,48,49]. Of the first six patients older than 16 years, five died of transplant-related complications (GVHD, infections) within the first 100 days. In view of this experience, early studies concentrated on patients under the age of 17 years.

Children and adolescents. Results in young patients were very encouraging, and in 1990, Lucarelli and his colleagues reported their experience through August 1988 in treating 222 consecutive patients under the age of 16 years [5]. All these patients received HLA-identical marrow, in 10 cases from parents and in the other cases from siblings, after conditioning with regimens containing BU 14 mg/kg and CY 200 mg/kg. One hundred and forty-one donors were heterozygous for β thalassemia and 81 donors were normal homozygotes. Five different regimens were used to prevent acute GVHD.

Analysis of the influence of pre-transplant characteristics on the outcome of transplantation was conducted in 116 patients who were all treated with exactly the same regimen. It was demonstrated that hepatomegaly and portal fibrosis were associated with a significantly reduced probability of survival. In multivariate analysis a history of poor compliance with the chelation regimen could not be distinguished from hepatomegaly as a predictor of survival and rejection-free survival. The influence of pre-transplant characteristics on the outcome of transplantation was reexamined in late 1989 [50] by which time 161 patients <17 years of age had been treated with the same regimen. The quality of chelation was characterized as regular when deferoxamine therapy was initiated no later than 18 months after the first transfusion and administered subcutaneously for 8–10 h continuously for at least 5 days each week. The chelation variable was defined as irregular for any deviation from this criterion. The degree of hepatomegaly (greater than or not greater than 2 cm), the presence or absence of portal fibrosis in the pre-transplant liver biopsy, and the quality of chelation (regular or irregular) given through the years before transplant were identified as variables permitting the categorization of patients into three risk classes. Class 1 patients had none of these adverse risk factors, class 3 patients had all three, and class 2 patients had one or two adverse risk factors. This analysis confirmed the prognostic significance for transplant outcome of risk class and the strong influence of the quality of chelation therapy.

By the end of December 2003, 524 patients <17 years of age had received HLA-identical transplants using regimens containing BU 14 mg/kg and CY 200 mg/kg. There were 145 class 1 patients, 333 class 2 patients, and 46 class 3 patients. The probabilities of survival, thalassemia-free survival, rejection and non-rejection mortality for class 1 patients were 90%, 87%, 3%, and 10%, respectively, and for class 2 patients they were 87%, 85%, 3%, and 13%, respectively (Table 71.1). The probabilities of survival, thalassemia-free survival, rejection and non-rejection mortality for the 46 patients in class 3 were 53%, 51%, 7%, and 42%, respectively, calculated at

Table 71.1 Pesaro experience of BMT for thalassemia from HLA-matched related donors between May 1985 and December 2003

	Class 1	Class 2	Class 3 (age <17 years) (since 1997)	Adult (age >17 years) (since 1997)
Patients, *n*	145	333	33	15
Protocols	6	6	26	26
Survival %	90	87	93	65
Thalassemia-free survival %	87	85	85	65
Death %	10	13	6	28
Rejection %	3	3	8	7

Table 71.2 Current treatment protocols

	Pre-conditioning	Conditioning	GVHD prophylaxis
Class 1 and Class 2 age >4 years	None	IV Bu Cy200	CSA/MP/short MTX
Class 1 and Class 2 age ≤ 4 years	None	IV Bu TT10 Cy200	CSA/MP/short MTX
Class 3 age ≤17 years	d-35 to -11 Az, Hu; d-16 to -11 Flu 150	IV Bu TT10 Cy160	CSA/MP/short MTX
Adults (age >17 years) Class 2–3	d-35 to -11 Az, Hu; d-16 to -11 Flu 150	IV Bu TT10 Cy 90	CSA/MP/short MTX

Az, azathioprine; Hu, hydroxyurea; Flu, fludarabine; Bu, busulfan; Cy, cyclophosphamide; TT, thiotepa; CSA, cyclosporine; MP, methylprednisolone; MTX, methotrexate.

15 years. In an attempt to improve results in class 3 patients, new treatment regimens consisting of BU 14 mg/kg and reduced doses of CY (160 or 120 mg/kg) were used between September 1989 and April 1997. These regimens improved the probability of survival in class 3 younger (age <17 years) patients from 53% to 79%, but were associated with an increase of rejection probability from 7% to 30%, probably due to inadequate immunosuppression and failure to eradicate the massive erythroid hyperplasia characteristic of these patients [51].

In April 1997, a new preparative regimen (Protocol 26) was adopted for class 3 patients <17 years of age in an attempt to decrease the 30% rejection rate without a corresponding increase in reappearance of the thalassemic clone. This protocol involved an intensified preparation with 3 mg/kg of azathioprine and 30 mg/kg hydroxyurea daily from day −45 from the transplant, fludarabine 20 mg/m2 from day −17 through day −13, followed by the administration of BU 14 mg/kg total dose and CY 160 mg/kg total dose. Prophylaxis against GVHD consisted of CY 7.5 mg/kg IV on day 1, methotrexate 10 mg/m^2 IV on days 3 and 6, and cyclosporine (CSP) 5 mg/kg IV daily from day −2 through day 5 reduced to 3 mg/kg/d IV until oral administration of 12.5 mg/kg/day could be tolerated. Continuous 24-h infusions of 40 mg/kg of deferoxamine via central venous catheter were initiated on day −45 and a regimen of hypertransfusion with RBCs was used to keep the level of hemoglobin between 14 and 15 g/dL. During this time interval patients received growth factors, granulocyte colony-stimulating factor (G-CSF) and erythropoietin twice weekly to maintain stem cell proliferation in the face of hypertransfusion, thereby facilitating the effect of the hydroxyurea. Protocol 26 was devised on the assumption that preparation with BU 14 mg/kg and CY 160 mg/kg was inadequate to eradicate thalassemic hematopoiesis in class 3 patients <17 years of age. Preliminary results of transplantation in 33 such patients treated with Protocol 26 showed the probabilities of survival, thalassemia-free survival, rejection and non-rejection mortality were 93%, 85%, 8% and 6%, respectively (Table 71.1 [52]). Interestingly this regimen improved the Kaplan–Meier probability of thalassemia-free survival for patients with class 3 thalassemia aged younger than 17 years at the time of the transplantation from 58% to 85% together with a reduction of the probability of rejection from 30% to 8% as compared with previous preparative regimens. The immunosuppressive qualities of fludarabine may have contributed to the effectiveness of this regimen.

Adult patients. Adult thalassemia patients have more advanced disease with both disease- and treatment-related organ complications mainly due to prolonged exposure to iron overload. From November 1988 through September 1996, 107 patients older than 17 years received transplants from matched donors. The median age for this population was 20 years (range 17–35 years). Eighteen patients were in class 2 and these received BU 14 mg/kg and CY 200 mg/kg. The other patients were in class 3 and received BU 14–16 mg/kg and CY 120–160 mg/kg. The probability of survival, thalassemia-free survival, rejection and non-rejection mortality for the entire group of these patients were 66%, 62%, 4%, and 37%, respectively [53,54]. For the 18 class 2 adults, the probabilities of survival and of thalassemia-free survival were both 76%.

From April 1997 all adult patients were prepared for transplantation according to Protocol 26 with the only difference that the dose of cyclophosphamide was reduced to 90 mg/kg total dose. The probability of survival, thalassemia-free survival, rejection and non-rejection mortality in 15 high-risk group patients were 65%, 65%, 7%, and 28%, respectively [55].

Current experience

In 2003, the authors of this chapter and two other transplant physicians moved from Pesaro to Rome where we started a new Transplant Program in the International Center for Transplantation in Thalassemia and Sickle Cell Anemia at the Mediterranean Institute of Hematology. Whereas the Pesaro experience was predominantly carried out on an Italian patient population, the Rome experience was characterized by two features: the patients were ethnically very heterogeneous, and the vast majority of these patients was not regularly transfused/chelated, or highly sensitized due to receiving RBC transfusions without the use of leukodepletion filters. Therefore, these patients were likely to have a higher risk of graft rejection as a result of sensitization to minor histocompatibility antigens. Taking these characteristics into consideration, we have modified the treatment protocols for transplantation of such patients (Table 71.2). As of September 2012, 24 class 1, 34 class 2, and 47 class 3 patients, younger than 17 years, received a first HSCT from an HLA-matched sibling donor at our institution. Initially 26 class 3 patients treated with original Protocol 26 had an elevated (15%) rejection probability. Therefore we modified this protocol in 2007 by increasing the dose of fludarabine in preconditioning and adding thiotepa to the conditioning regimen to further decrease rejection in this group of patients. Since then we have treated 20 class 3 patients with the modified Protocol 26. The preliminary results showed that none of the patients had rejection and thalassemia-free survival was 84% [56]. Figures 71.1, 71.2 and 71.3 show the probability of survival, thalassemia-free survival, rejection, and TRM for class 1, class 2, and class 3 patients, with a median follow-up of 65 months (range, 1–97 months) for surviving patients.

Outcome of haploidentical transplantation for thalassemia will be discussed later.

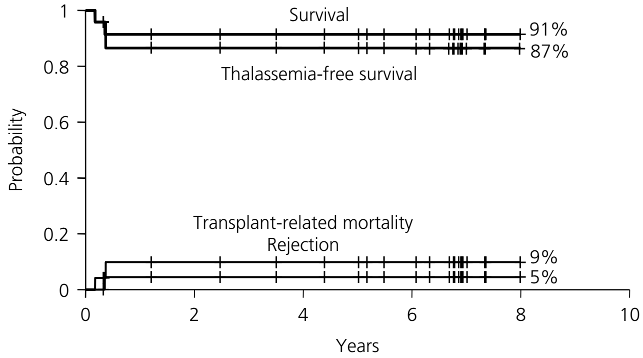

Figure 71.1 Estimates of survival, thalassemia-free survival, non-rejection mortality and rejection for 24 class 1 patients with median age of 3 years (range, 2–6 years) and treated with oral (14 mg/kg) or IV busulfan (weight-based dosing), cyclophosphamide 200 mg/kg and ± thiotepa 10 mg/kg.

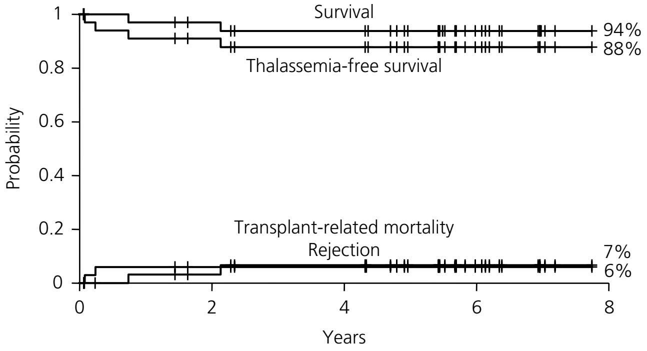

Figure 71.2 Estimates of survival, thalassemia-free survival, non-rejection mortality and rejection for 34 class 2 patients with median age of 7 years (range, 2–16 years) who were treated with oral (14 mg/kg) or IV busulfan (weight-based dosing), cyclophosphamide 200 mg/kg and ± thiotepa 10 mg/kg.

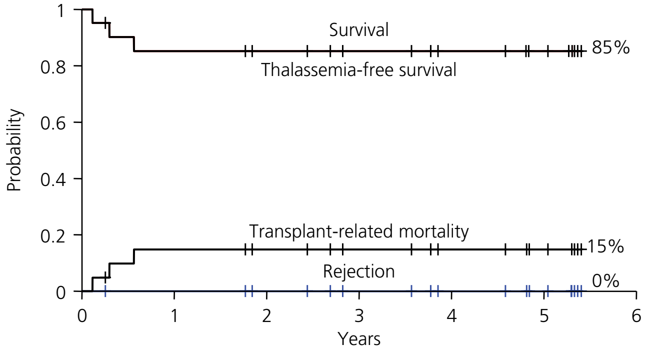

Figure 71.3 Estimates of survival, thalassemia-free survival, non-rejection mortality and rejection for 20 class 3 patients with median age of 9 years (range, 6–16 years) who were treated with the modified Protocol 26 (preconditioning with Hu30Az3Flu150 and conditioning with IV BuTT10Cy160).

Graft failure or rejection. Patients with engraftment failure and without functioning marrow have a bleak prospect because an early second transplant with a second course of conditioning is usually not a reasonable option. However, occasionally patients have late graft failure without thalassemia recurrence and in this situation second transplant attempts with intensive conditioning may provide the only treatment option to offer a chance of prolonged survival.

Patients who reject their grafts and have a return of host hematopoiesis do not have an urgent need for second transplants, and such interventions can be delayed until the toxic effects of the conditioning regimen for the first transplants have resolved. At least a year should be allowed to elapse between the first and second transplant. Our historical experience with second transplants showed a low thalassemia-free survival rate and a high rate of graft rejection [57].

In 2003, we devised a new treatment protocol for second transplants in patients with thalassemia aimed at reducing the high graft rejection rate and increasing disease-free survival. Sixteen patients with thalassemia recurrence following rejection of the first graft, with a median age of 9 years (range, 4–20 years), were given second transplants using bone marrow or PBSC [58]. All but two patients received stem cells from the same donor. The sustained engraftment rate was high (94%), with only one patient having graft failure. The rates of survival, thalassemia-free survival, graft failure, and TRM were 79%, 79%, 6%, and 16%, respectively showing that this treatment protocol is highly effective in terms of sustained engraftment and event-free survival.

Graft-versus-host disease. Graft-versus-host disease (GVHD) is one of the principal causes of morbidity and mortality after allogeneic HCT. In a recent prospective study we have evaluated GVHD in children underwent BMT for thalassemia [59]. All patients were given cyclosporine (CSA), methylprednisolone and a modified short course of MTX (CYorMTX on day +1, and MTX on days +3 and +6) as GVHD prophylaxis. The incidence of grade II–IV and III–IV acute GVHD was 35% and 9%, respectively. In multivariate analysis, high CD3+ (HR 4.6; 95% CI 1.4–14.7; $p = 0.010$) and CD34+ (HR 4.3; 95% CI 1.4–12.7; $p = 0.011$) cell doses were associated with grade II–IV aGVHD. Using a quartile cutoff point analysis we found a minimum threshold for $CD3^+$ (38×10^6/kg) and $CD34^+$ ($4 + 10^6$/kg) cells above which the incidence of grade II–IV aGVHD is significantly increased. In an attempt to decrease the incidence of acute GVHD patients receiving $CD3^+$ and/or $CD34^+$ cell doses above these thresholds are now given day +11 MTX. Cumulative incidence of extensive cGVHD was 10%.

Mixed chimerism (MC) after BMT in thalassemia. Ablation of all host HSCs is usually considered necessary to establish conditions for stable and complete marrow engraftment of donor stem cells [complete chimerism (CC)]. However, we have observed that MC is not unusual in transplanted thalassemic patients. Further, MC may be transient (TMC) when it evolves into CC or graft rejection, or persistent MC (PMC) when the coexistence of donor and recipient cells is longer than 2 years, with hemoglobin levels sufficient for a good quality of life without RBC transfusion [60]. When PMC was detected using sensitive techniques [61], it could be demonstrated in all the nucleated hematopoietic cell subpopulations of the marrow and peripheral blood. In informative situations, all circulating mature RBCs were of the same blood group as the donor, even when 70% of burst-forming units – erythroid (BFU-E) were of host origin.

In a group of 335 mostly consecutive patients, all with 2 or more years of post-transplant follow-up, the incidence of MC was 32.2% at

2 months after HCT. This proportion decreased to 10.1% at 2 years after transplantation and remained stable thereafter. Within this group there were 185 class 1 or 2 patients, all treated with the same pretransplant conditioning regimen (BU 14 mg/kg and CY 200 mg/kg). For these patients, the incidence of MC at 2 months after the transplant was 21%, while it was 54.9% in the group of the remaining 150 patients who were treated with the same dose of BU and a reduced dose CY (120 mg/kg or 160 mg/kg). The incidence of PMC 2 years after transplant was 10.1% in each of the two groups of patients, although they were not homogeneous for the preparative regimen. Graft rejection did not occur in any of the 227 patients with CC early after HCT whereas it occurred in 35 of the 108 patients (32.4%) with MC detected during the first 2 months after HCT.

Rejection was related to the number of residual host cells (RHCs) present in patients with TMC early after HCT [61]. A classification scheme for MC was adopted [61] in which the presence of <10% RHCs was designated as level 1, RHCs between 10% and 25% was categorized as level 2, and RHCs >25% was categorized as level 3. Of the 108 patients who at 2 months after the transplant were MC, 61 patients had level 1, 27 patients had level 2, and 20 patients had level 3 chimerism. In the group of level 1 patients, 57% eventually developed CC, 13% rejected the transplant, and 30% became PMCs. In the group of level 2 patients, 44% became CC, 41% rejected the transplant, and 15% remained PMCs. Eighteen of the 20 patients with level 3 MC rejected the transplant, while only two developed PMC.

Thirty-four ex-thalassemic patients after transplant have maintained PMC for 2–13 years and are transfusion-independent with hemoglobin levels ranging from 8.3 g/dL to 14.7 g/dL [61]. Fifteen of these patients showed level 3 PMC with large numbers of recipient precursor cells. In some patients, the proportion of donor engrafted cells decreased to levels usually predictive of complete rejection. One of these 15 patients who received BMT in 1998 showed progressive increasing of RHCs on annual follow-ups, although her hemoglobin level maintained between 10 and 11 g/dL until late 2005, when the patient became anemic with the percentage of donor cells of 5%. The patient became again transfusion-dependent and a successful second transplant from the same donor was performed in May 2006 [62]. This latest rejection with autologous reconstitution demands lifelong monitoring of the chimerism status in patients with PMC. It is not known why MC is transient in some patients, and remains persistent in others. Clones of regulatory T cells may develop in some patients with PMC and establish a state of reciprocal tolerance. Further studies are needed of the mechanisms underlying this state of tolerance to permit the design of protocols that will produce it predictably. The discovery of this phenomenon has potential importance for the future use of gene therapy and for the adoption of less toxic conditioning regimens as preparation for transplantation. These findings suggest that patients with a high risk of rejection can be identified soon after transplantation permitting the application of preemptive treatment strategies aimed at preventing rejection.

HCT from alternative donors

HCT from alternative related donors. A major limitation to the successful use of transplantation is the limited number of HLA-matched related donors. Between 30% and 35% of patients with hemoglobinopathies have such a donor. The curative potential of transplantation for hemoglobinopathies has encouraged the use of hematopoietic cell donations from donors other than HLA-matched sibling donors (alternative donors).

Our previous experience with transplantation in thalassemia using alternative related donors (either phenotypically identical or 1- to 3-antigen mismatched donors) was not successful. Outcomes were poor with high rates of rejection and GVHD, and low thalassemia-free survival rates [63]. The results of this study clearly showed that the conditioning regimens used were not adequately myeloablative and immunosuppressive to ensure a high sustained engraftment rate, prevent severe GVHD, and promote a high thalassemia-free survival probability. Therefore, we adopted a new intensified treatment protocol (Pc 26.1) for alternative donor transplantation in thalassemia. The Pc 26.1 was initially designed for second transplants [59], but the very encouraging results led us to also apply it in patients receiving transplants from donors who are not HLA-matched siblings. Sixteen thalassemia patients with median age of 9.6 years (range, 1.4–24 years) who received BMT from phenotypically HLA-identical ($n = 11$) or 1-antigen mismatched relatives ($n = 5$) were treated according to this new protocol [64]. All patients had sustained engraftment. One patient died due to chronic GVHD-related causes. The probability of overall survival, thalassemia-free survival, and transplant-related mortality were 94% (95% CI, 63–99%), 94% (95% CI, 63–99%) and 6% (95% CI, 1–26%), respectively. These data showed that the novel treatment protocol Pc 26.1 effectively and safely prevented graft rejection and ensured a high thalassemia-free survival rate in patients who received BMT from related donors who were not HLA-matched siblings. Importantly, the use of phenotypically matched or 1-antigen mismatched related donors resulted in outcomes similar to the use of matched sibling donor grafts. Our data support the use of related HLA-phenotypically matched or 1-antigen mismatched donors as an acceptable alternative to matched unrelated donors in patients with thalassemia.

Haploidentical stem cell transplantation. To further extend the donor availability for those patients who lacked a matched suitable donor, in 2002 we started a haploidentical T-cell-depleted HCT program for thalassemia. To be eligible for this study patient should lack an HLA-matched either related or unrelated donor or have red-cell alloimmunization rendering transfusion impossible or life-threatening. Twenty-two patients with transfusion-dependent thalassemia and a median age of 7 years (range, 3–14 years) were given stem cell grafts from haploidentical mothers ($n = 20$) or brothers ($n = 2$) between 2002 and 2008. All of the patients received an intensified preparative regimen consisting of 3 mg/kg azathioprine and 60 mg/kg hydroxyurea daily from day −59 from the transplant, and fludarabine (FLU) 30 mg/m^2 from day −17 through day −13, aimed at reducing hyperplastic bone marrow and gradually increasing immunosuppression to avoid unacceptable peritransplant drug toxicity. During this time frame, the patients also received hypertransfusion to suppress endogenous erythropoiesis, and granulocyte colony-stimulating factor and erythropoietin to maintain stem cell proliferation, thus facilitating the effect of hydroxyurea. Conditioning regimen consisted of BU14/thiotepa (TT)10/CY200 and antithymocyte globulin (ATG-Fresenius). Patients received cyclosporine for GVHD prophylaxis for the first 2 months after transplantation. As stem cell source, eight patients received T-cell-depleted PBSC (CD34$^+$ immunoselected) and CD3$^+$/CD19$^+$ immunodepleted bone marrow stem cells. The last 14 patients received CD34$^+$ selected peripheral and bone marrow stem cells, using the CliniMACS® procedure. Median infused cell doses were: CD34$^+$ 15.2 × 10^6/kg, CD3$^+$ 1.8 × 10^5/kg, and CD19$^+$ 0.27 × 10^6/kg in the first eight patients, and

$CD34^+$ 14.2×10^6/kg, $CD3^+$ 2×10^5/kg, and $CD19^+$ 0.19×10^6/kg in the last 14 patients. Overall, six patients rejected their grafts, two patients died of Epstein–Barr virus-related cerebral lymphoma or cytomegalovirus pneumonia, and 14 patients are alive and cured of thalassemia. The rates of survival, thalassemia-free survival, rejection and non-rejection mortality were 90%, 61%, 29%, and 14%, respectively [65]. Although younger patient age and megadose of $CD34^+$ cell-containing grafts, immune reconstitution, especially $CD4^+$ cell recovery, was delayed beyond 1 year in most patients [66]. These data showed the feasibility of haploidentical stem cell transplantation for patients with thalassemia and, therefore, this procedure should be considered for those younger patients who lack a suitable HLA-matched related or unrelated donor.

HCT from unrelated donors. Results of HCT from unrelated donors for the treatment of malignant disease have improved steadily, mainly due to the introduction of high-resolution molecular techniques for histocompatibility testing and improvements in the management of post-transplant complications. These results have stimulated the use of HCT from unrelated donors for the treatment of hemoglobinopathies. The Italian Cooperative Group for Bone Marrow Transplantation has recently reported results obtained in 32 thalassemic patients (aged 2–28 years) who received bone marrow from unrelated donors [67]. Four patients were in class 1, 11 were in class 2, and 17 were in class 3 of risk. The first 4 patients received Bu and CY, and the remaining 28 patients BU 14 mg/kg, TT 10 mg/kg and CY. The dose of CY was 200 mg/kg for class 1 and class 2 patients and it was 120 mg/kg or 160 mg/kg for class 3 patients aged >16 years old. Prophylaxis against GVHD included CSP and a short course of MTX. The probability of thalassemia-free survival and non-rejection mortality was 66% and 25%, respectively for the entire group of patients. Although the difference was not significant, five of the six patients who died belonged to class 3. The incidences of grade II–IV acute and chronic GVHD were 41% and 25%, respectively. Patients who shared at least one extended haplotype had less acute or chronic GVHD and better survival. Updating the observations of these centers to 44 patients, the probabilities of survival, thalassemia-free survival, rejection and non-rejection mortality are 79%, 68%, 12%, and 23%, respectively. These data are encouraging and show that the results of HCT from well-selected unrelated donors might be comparable to those of HLA-identical sibling transplants, especially in patients with less advanced disease.

Recently this group has reported data on 27 adult thalassemia patients (aged 17–37 years) transplanted from unrelated donors selected by high-resolution HLA molecular typing [68]. Fifteen patients received BU14 mg/kg, thiotepa 10 mg/kg, and CY 160 mg/kg (nine patients) or CY 120 mg/kg (six patients). In view of the high mortality in these patients the subsequent 11 patients were given BU 14 mg/kg and CY 120 mg/kg. GVHD prophylaxis consisted of CSP and a short course of MTX. Three patients were also given antithymocyte globulin. The probability of survival, thalassemia-free survival, transplant-related mortality and rejection were 70%, 70%, 30%, and 4%, respectively. The incidence of grade II–IV acute and chronic GVHD was 37% and 27%, respectively. Although limited these data show that unrelated marrow transplantation not only in younger patients but also in adult patients from well-selected donors may offer a success rate similar to those obtained from HLA-identical sibling transplantation. The main limitation of the experience with unrelated BMT for thalassemia is that, using such stringent criteria, only about one third of thalassemia patients who started the search found a suitable donor in a median time of 3–4 months. One possibility to increase the donor pool could be adopting less stringent criteria of HLA matching for donor selection allowing one or two allelic disparities, but the results of such transplants remain to be determined.

HCT from unrelated cord blood. Hematopoietic stem cell transplantation from an unrelated cord blood (UCB) donor is, now, standard practice for the treatment of hematologic malignancies. The number of UCB transplants has increased dramatically, because several studies have demonstrated that results from HLA-mismatched UCB transplants were comparable to those from HLA-matched unrelated bone marrow transplants in children [69]. Advantages such as faster availability, tolerance of one to two HLA mismatches, and low incidence of acute GVHD made UCB transplants attractive for patients with some non-malignant diseases [70]. In a recent Eurocord/CIBMTR/NY Blood Center study researchers evaluated the outcome of 51 patients with thalassemia ($n = 35$, median age 4 years) and sickle cell disease ($n = 16$, median age 6 years) treated with unrelated cord blood [71]. Seven patients received 6/6 matched (HLA-A, -B antigen, and -DRB1 allele levels), 18 patients 5/6 matched, 25 patients 4/6 matched, and one patient 3/6 matched cord blood grafts following myeloablative ($n = 39$) or reduced-intensity ($n = 12$) conditioning regimens. Most patients were also given ATG or alemtuzumab before transplantation. Overall and disease-free survival for patients with thalassemia and sickle cell disease were 62% and 94%, and 21% and 50%, respectively. However, a more recent study from China reported very encouraging results. Thirty-five thalassemia patients with median age of 5.5 years (range, 1.2–14) were given 6/6 matched ($n = 8$), 5/6 matched ($n = 16$), 4/6 matched ($n = 27$), and 3/6 matched cord blood grafts following myeloablative conditioning with BUCYATG [72]. The incidence of rejection was 17%, and it was 82% for grade II–IV acute GVHD and 35% for chronic GVHD. The probability of overall survival and thalassemia-free survival was 88.3% and 78.9%, respectively. Genetic homogeneity in the Chinese population might explain the differences in outcomes between the two studies.

Non-myeloablative or reduced-intensity hematopoietic stem cell transplantation. Unlike hematologic malignancies where mixed chimerism may predict relapse, in non-malignant disorders, the development of stable mixed chimerism has a potential for ameliorative effect that was well documented for β-thalassemia major and sickle cell anemia [61,73]. It appears that when stable mixed chimerism is established, even a minority of donor cells is sufficient to overcome an underlying genetic defect. These observations have provided the rationale for using non-myeloablative or reduced preparatory regimens in patients with thalassemia or sickle cell anemia, which may reduce the toxicity of transplantation especially in patients with advanced disease. Non-myeloablative conditioning followed by allogeneic transplantation has been tested in limited clinical series that rely upon immunosuppressive rather than ablative preparatory regimens to facilitate donor cells engraftment. Recently, seven patients (aged 3–20 years) with sickle cell anemia or thalassemia and given stem cell transplantation following a preparative regimen consisting of fludarabine, low-dose (i.e., 200 cGy) total body irradiation, and antithymocyte globuline (in two patients) have been reported [74]. Although transplant-related toxicity was minimal, and many patients had transient engraftment, all eventually rejected their donor graft. In a recent study, results of reduced-intensity HCT using peripheral blood stem cells from siblings or unrelated matched donors after preparatory regimen with fludarabine (180 mg/m^2 total

Table 71.3 Transplants for thalassemia. Reports from centers other than Pesaro

*By risk category, survival = best risk/worst risk.

dose), IV busulfan (6.4 mg/kg total dose) and an equine antithymocyte globuline (160 mg/kg total dose) in patients with SCA (three patients) or β thalassemia (one patient), were not encouraging: only one out of four patients had sustained engraftment [75].

These results indicate that stable donor engraftment after non-myeloablative or reduced-intensity HSC transplantation is difficult to achieve among immunocompetent patients with hemoglobinopathies. Therefore, patients with thalassemia or sickle cell disease need more intensive myeloablative conditioning regimens because graft failure in these patients is not a negligible problem even when a conventional myeloablative preparative regimen is administered [4,5,67]. These conditioning regimens should be studied in selected higher risk thalassemia patients with advanced disease along with organ damage who might have a higher transplant-related toxicity after conventional myloablative transplantation.

Experience at other transplant centers

At present more than 3000 BMTs for thalassemia have been performed worldwide with the probability of overall and thalassemia-free survival greater than 90% and 80%, respectively in low/intermediate risk patients [76]. Table 71.3 reports the outcome of transplantation from different countries [77–87]. In Italy the Pescara group has been particularly active, reporting 115 patients transplanted through 2006 [77].

Management of the ex-thalassemic patient after HCT

After transplantation, ex-thalassemic patients still carry the clinical complications acquired during years of transfusion and chelation therapy. Among the issues requiring long-term management in such patients are iron overload, chronic hepatitis, liver fibrosis, and endocrine dysfunction.

There is no reason to expect that BMT will eliminate the excess iron acquired during years of thalassemia, since spontaneous iron elimination occurs very slowly. In our experience, serum ferritin and transferrin saturation spontaneously return to normal levels only in class 1 patients [88]. Persisting tissue iron overload can cause significant morbidity and mortality similar to that seen in hereditary hemochromatosis [89]. Thus iron removal is indicated in all transplanted thalassemic patients who have evidence of persisting iron overload, and initiating a sequence of phlebotomies or restarting chelation with deferoxamine at 18 months post-HCT achieves this best.

Excess iron can be completely removed from the body and a body iron content within the normal range can be achieved. The necessary duration of treatment is directly correlated with the magnitude of the iron overload, and ranges from a few months to several years [90]. In most ex-thalassemics, reduction or normalization of the iron pool results in marked improvement in serum levels of liver enzymes and in the histological activity index [91]. The serum aminotransferases and the histological activity index normalized after iron depletion in about half of the patients who were seropositive for hepatitis C virus (HCV), suggesting that iron is a cofactor of HCV for liver disease [91]. Ex-thalassemics with early cardiac involvement, characterized by systolic and/or diastolic dysfunction, show complete regression of these subclinical cardiac abnormalities after iron depletion [92].

Infection with HCV is common in thalassemic patients, particularly in those transfused before second-generation enzyme-linked immunosorbent assay (ELISA) tests became available for detecting HCV in donated blood. In thalassemia, liver damage due to HCV infection is exacerbated by iron overload, and liver disease is a recognized cause of mortality and morbidity. In fact, analysis of the natural history of liver fibrosis following BMT for thalassemia showed that iron overload and hepatitis C infection are independent risk factors for liver fibrosis progression, and their concomitant presence results in a striking increase in risk [93].All the donors in this series of patients were HCV seronegative. After HCT, approximately 10–15% of HCV-infected patients become HCV seronegative [94]. This may reflect complete elimination of the virus, but we cannot be sure of this. However, seropositivity has not returned in these patients. The chronic risk of conditions associated with HCV infection, such as chronic hepatitis, cirrhosis, and hepatocellular carcinoma, persists in the remaining patients. The precise risk of developing one of these complications in ex-thalassemics is uncertain. Transplanted thalassemics have a long, probably normal life expectancy and mild chronic liver disease has to be considered in this perspective. Chronic HCV infection and transplant-related complications are probably the only factors that may limit survival in ex-thalassemics. Thus, avoidance of progression of liver damage to cirrhosis must be a primary goal. Treatment for chronic hepatitis C has improved over the last two decades. Present standard therapy is peginterferon alfa/ribaverin for adults and children without thalassemia [95]. Concern about ribavirin-induced hemolysis and worsening of the anemia and iron overload limit the use of this therapy in patients with thalassemia. Ex-thalassemics with complete donor chimerism and chronic hepatitis C will experience a similar spectrum of side effects to those of patients without thalassemia. Therefore ex-thalassemics should be offered treatment with the peginterferon alfa/ribaverin combination after they have completed their iron depletion program.

It is well known that growth failure and endocrine dysfunction are common in thalassemia major patients treated by conventional treatment. While the endocrine dysfunction is usually due to iron overload as a result of chronic transfusions, in growth failure lifelong desferrioxamine treatment also plays a negative role in these patients. Although the role of busulfan-containing regimens on growth velocity after transplant remains controversial, the negative effect of this regimen on gonadal damage is well documented. Age at the time of transplant in β-thalassemia patients is an important predictor of growth. In fact, children receiving transplant before 8 years of age showed a normal growth rate, while older children, class 3 patients, and patients who developed chronic GVHD had impaired growth [96]. Gonadal damage is a common side effect of busulfan- cyclophosphamide conditioning. Indeed, approximately one third of boys and two thirds of girls failed to spontaneously enter puberty following transplant [97]. Nevertheless, some patients can restore their fertility after transplant which is supported by our observations of nine successful pregnancies and six spontaneous paternity in our patients (unpublished data). These data demonstrate that patients exposed to BUCY regimen are not inevitably infertile.

One of the major late complications of BMT is chronic GVHD, which is the principal cause of morbidity and non-relapse mortality. Most of our patients developed a limited form of chronic GVHD and the probability of a moderate or severe form was only 8% and 2%, respectively [59,98].

With the increasing number of transplant survivors there is a risk for secondary malignancies. Patients who received BMT for β thalassemia and sickle cell disease in Pesaro had a low incidence (1.3%) of malignancies (unpublished data). The type of malignancies consisted of three early and one late non-Hodgkin lymphomas, four solid tumors (squamous cell carcinoma, Kaposi sarcoma, melanoma, and colon cancer, respectively), and two acute myeloid leukemias. Six of these patients are alive and well.

The role of HCT in the treatment of thalassemia

Hematopoietic cell transplantation is the only treatment able to definitively cure thalassemia. The results of transplantation from HLA-identical family members are clear. Class 1 patients have a very high probability of cure with a very low early and late morbidity and mortality. There is no reason to deny these patients the advantages of a life free from daily tedious, expensive, and uncomfortable therapy. We still do not know the probability that a patient receiving conventional therapy will deteriorate into a worse risk category, but the fact is that transplant centers are often confronted with patients in risk classes 2 and 3 who represent failures of conventional treatment. Delaying transplantation until the patient is in a risk category beyond class 1 substantially reduces the probability of transplant success and jeopardizes the reversibility of liver and cardiac damage. We therefore believe that all patients with β thalassemia who have HLA-identical related donors should be transplanted as soon as possible. Patients without such donors who have well-selected unrelated donors should also be considered for HCT.

CHAPTER 72

Hematopoietic Cell Transplantation for Sickle Cell Disease

Mark C. Walters
Blood & Marrow Program, Division of Hematology/Oncology/BMT, UCSF Benioff Children's Hospital Oakland, Oakland, CA, USA

Introduction

Sickle cell disease (SCD) is caused by a single point mutation in codon 6 of the β-globin chain. This mutation directs an amino acid substitution of valine for glutamic acid, which promotes the formation of long hemoglobin polymers under hypoxic conditions [1–3]. This propensity for polymer formation deforms the red blood cell (RBC) and causes significant alterations in red cell integrity, rheologic properties, and life span [4]. It is probably directly or indirectly responsible for the vasculopathy that forms in virtually all body organs. This heritable disorder of hemoglobin affects one in every 375 African Americans in the United States. Worldwide, nearly 300,000 infants are born annually with SCD, the majority in Africa [5]. In the United States, 2000 new births occur annually [6].

Ever since the initial report in 1984 of successful hematopoietic cell transplantation (HCT) in a child who had acute myelogenous leukemia and SCD who was cured of both, hematologists and transplantation physicians have struggled with how to make this curative therapy available to a wider group of affected individuals [7]. During the intervening years, a better understanding of the natural history of SCD has emerged, and views about who might benefit most from this intensive procedure have evolved to include more, not fewer, individuals [8]. However, this appreciation of the severity of SCD has not translated into greater utilization of HCT, particularly in children. This has occurred, in part, due to improved survival to adulthood among children identified by newborn screening programs and with the broader administration of hydroxyurea in children and adults to mitigate the frequency of vaso-occlusive clinical events. Of interest, the utility of HCT was questioned in the recent *Evidence-Based Management of Sickle Cell Disease* treatise published in 2014 by the National Heart, Lung, and Blood Institute in which the expert panel concluded that "additional research is still needed that addresses the potential risks of this therapy (e.g., failure of engraftment and chronic graft-versus-host disease) before HCT can become a widely used therapy" [9]. However, the median survival among adults with SCD has not changed significantly over the past three decades [10]. Thus, the curative potential of HCT for SCD remains an important therapeutic option for the indications of stroke, recurrent vaso-occlusive events, and other clinically significant complications that impact life span and quality of life in the long term. Ultimately, as most patients who might otherwise be suitable candidates for HCT lack a sibling donor, the most important progress must occur in the arena of alternative donor HCT for SCD, which remains in a nascent phase of development. Thus, this chapter concludes with reference to ongoing clinical trials that might expand HCT to include more of those who might benefit.

Epidemiology and etiology

Although first reported in the medical literature in 1910 as a disorder characterized by its peculiar alteration in RBC morphology, SCD was recognized many generations earlier in Western Africa, where it was called by various local names that reflected its most common feature, which is recurrent pain. Thus, well-established tribal names for the disorder including "The Ga *Chwechweechwe*, the Fante *Nwiiwii*, the Ewe *Nuiduidui*, the Akan *Ahotutuo* all reflect the onomatopoeia of the repetitive gnawing pains characteristic of sickle cell crisis" [11]. The path of discovering the molecular determinant of SCD focused on the most likely suspect, hemoglobin, the most abundant protein in the misshapen RBC. In 1949, Pauling showed that the sickle RBC contained hemoglobin that had an altered electrophoretic mobility, and reasoned that SCD must be a disorder of hemoglobin [1]. Shortly thereafter, Neel and his colleagues showed that RBCs from patients with SCD could be induced to sickle, and also showed that this phenomenon was inherited as an autosomal recessive disorder [12]. Finally, in 1957, Ingram showed that the cause of SCD was an amino acid substitution of valine for glutamic acid at the β-6 position of the globin chain, which subsequently was determined to follow a single base pair change in the coding DNA [3].

Based upon estimates, it appears that the sickle mutation independently originated from regional populations in Africa and Saudi Arabia approximately 70,000–150,000 years ago [13]. It is generally believed that the persistence of the sickle gene in the African and Mediterranean regions follows from its conferring a reduced risk of infection and mortality from infection by *Plasmodium falciparum*, the malaria parasite [14]. However, infants and young children with sickle cell anemia (homozygous HbSS) in particular are at high risk of dying from malaria, which accounts in part for the significant early mortality of sickle cell anemia in certain regions of Africa [14]. Nonetheless, protection from malaria appears to be conferred in a dose-dependent manner relating to the HbS content in the RBC, with those having sickle cell anemia conferring the greatest natural resistance to malaria infection.

Hb, hemoglobin; Hb S, sickle hemoglobin. Gene variants: *Hb SS*, sickle cell anemia (includes *Hb S*-β^0-thalassemia); *Hb AS*, sickle cell trait; *Hb SC*, sickle hemoglobin C disease; *Hb SD*, sickle hemoglobin D disease; *Hb SE*, sickle hemoglobin E disease.

It is estimated that between 80,000 and 100,000 persons in the United States are affected by SCD [15]. The frequency of the sickling hemoglobin disorders, as illustrated by the experience of the California Newborn Screening Program, is presented in Table 72.1, and indicates that the majority of affected individuals in the United States are of African descent [16]. However, individuals of Mediterranean, Caribbean South and Central American, Arab, and East Indian descent also are at risk for SCD. Together, these disorders also contribute to a larger national and worldwide public health concern, by virtue of the impact of SCD on individuals and healthcare systems. In the United States alone, the medical cost of caring for approximately 80,000 affected individuals exceeds $1 billion [17].

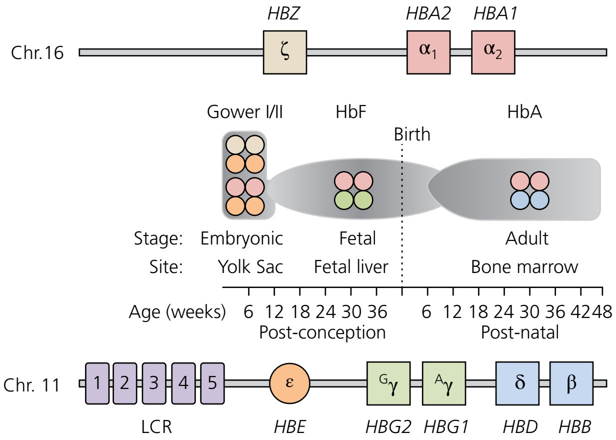

Figure 72.1 Schematic representation of the human α-globin and β-globin loci with temporal expression during ontogeny. The gene order of the α-globin locus on chromosome 16 and the β-globin locus on chromosome 11 is shown with each temporal stage, as indicated on the timeline at bottom. The types of hemoglobin tetramers produced for each indicated site are shown. LCR, locus control region; HbF, fetal hemoglobin; HbA, adult hemoglobin. Source: Wilber et al. 2011 [141]. Molecular and cellular biology

The genes that encode the α- and β-globin polypeptides that together account for the hemoglobin tetramer reside on human chromosomes 16 and 11, respectively [18]. Expression of the α- and β-globin proteins is coordinately regulated to avoid polypeptide chain imbalance, the proximate cause of ineffective erythropoiesis in profound inborn examples of chain imbalance such as thalassemia major. The globin loci contain arrays of genes that are expressed sequentially during the course of erythroid ontogeny, and this regulation includes a developmental switch at the transcriptional level of control, which coincides with an alteration in the site of erythropoiesis during embryonic development and in RBC morphology, common characteristics of erythropoiesis in vertebrate animals (Figure 72.1). With regard to SCD, the most clinically important developmental switch occurs during the transition from fetal γ globin to adult β globin at birth, at which time the antisickling fetal hemoglobin is replaced by the polymer-prone HbS, and the clinical features of SCD begin to emerge.

Elucidating the molecular mechanism of the γ to β globin switch has been the focus of intense investigation and a better understanding of the control of fetal hemoglobin expression was recently elucidated. There is general agreement that γ-globin transcription is silenced in erythroid progenitor cells developing in the postnatal marrow, and the presence of a transcriptional repressor was long suspected, but until recently, elusive. Genome-wide association studies performed in individuals with and without hemoglobin disorders discovered two loci outside the globin locus located on chromosome 2 (BCL11A) and chromosome 6 (HBS1L-MYB) that accounted for a significant fraction of individual variation in HbF level [19–21]. BCL11A is a transcription repressor, and when its level of expression was decreased in human primary adult erythroid progenitor cells, HbF expression levels were increased [22]. When BCL11A expression was eliminated by homologous recombination in mice, physiologic silencing of murine embryonic and transgenic humanγ-globin genes was impaired [23]. In addition, BCL11A binds to sites in the human β-globin locus specifically deleted in hereditary persistence of fetal hemoglobin (HPFH) syndromes [24,25]. Thus, it is very likely that BCL11A coordinates the hemoglobin switch, perhaps by participating in a multiprotein complex. It is very clear that the abrogation of this switch with persistent γ-globin transcription has an ameliorative effect on the clinical expression of SCD as occurs when HPFH is co-inherited with SCD. As a consequence of these recent discoveries, targeting the γ to β molecular switch by pharmacologic discovery to elicit persistent HbF expression is under development [26]. In addition, replacement gene therapy to repress BCL11A expression or to express γ globin or other antisickling globins in gene delivery systems that ensure long-term expression for a potent and durable antisickling effect are nearing clinical phase I testing [27].

In the absence of an antisickling hemoglobin, there is a strong propensity for sickle hemoglobin polymerization, and consequently vaso-occlusion, which is the clinical hallmark of this disorder. The phenomenon of vaso-occlusion originates in sickle hemoglobin, which, in the deoxygenated state, tends to form polymers that deform the RBC and diminish its biochemical and structural integrity. While the causal relationship between sickle hemoglobin and vaso-occlusion is not disputed, the contributing factors and sequence of events that ultimately impair the flow of blood in both small and large blood vessels are complex but are being elucidated. The deoxygenated sickle polymer induces cellular potassium and water efflux, caused both by acidification and cellular swelling, which activates the potassium–chloride co-transport efflux pathway [28], and by cellular membrane distortion, which, with the accompanying transient calcium influx, activates the calcium-dependent Gardos channel pathway of potassium and water efflux [29]. The resulting cellular dehydration increases the cell density and sickle hemoglobin concentration, thereby promoting sickle hemoglobin polymerization. The clinical influence of these cellular conditions, as defined by the percentage of circulating dense RBC, is expressed by a strong association with complications such as skin ulcers and priapism [30].

Sickle hemoglobin polymerization also induces perturbations in erythrocyte cellular membranes, which promote adhesive interactions with vascular endothelial cells (reviewed in [31]). These interactions impact factors that control the vascular tone of blood vessels, and generally elicit vasoconstriction. Other cellular blood components are affected by these events, importantly granulocytes and activated platelets that interact with adhesive sickle erythrocytes and endothelial cells. Reticulocytes released prematurely from marrow also express membrane proteins that promote erythrocyte–endothelial cell interactions [32]. These cellular interactions ultimately generate the release of cytokines that promote an inflammatory response and amplify the cascade of vaso-occlusion and tissue injury. None of these factors alone can explain vaso-occlusion, although they may contribute singly or in a combinatorial manner. As a result, the cause and severity of vaso-occlusion may vary from event to event, and from individual to individual.

The recurrent ischemic/hypoxic insults that occur with intravascular sickling cause chronic organ injury. One of the signaling molecules associated with hypoxia is adenosine, and this signaling molecule is expressed at high levels during vaso-occlusive episodes [33]. Under normal physiologic conditions, an ischemic/hypoxic event generates ATP and thereby adenosine, which promotes the production of 2,3 bisphosphate glycerate (2,3-BPG) by signaling through an erythroid-specific stimulatory G-protein receptor, ADORA2B. Upon its accumulation in the RBC under physiologic conditions, 2,3-BPG causes the oxygen-hemoglobin dissociation curve to shift rightward and thus it facilitates oxygen delivery in a hypoxic environment. However, the liberation of adenosine under these conditions in sickle cell anemia elicits a pathophysiologic response, as it promotes deoxygenation of sickle hemoglobin, promotes sickle hemoglobin polymerization and thus vaso-occlusion. Recent studies by Xia and colleagues showed that 2,3-BPG levels are elevated in SCD, and in a murine sickle model, this effect can be abrogated by exposure to theophylline and other ADORA2B receptor antagonists or by the administration of PEG-adenosine deaminase, a pegylated enzyme that lowers adenosine levels [34]. It was demonstrated that by lowering the adenosine concentration in a mouse model of SCD, it was possible also to reduce 2,3-BPG, increase oxygen-binding capacity, and attenuate intravascular sickling. Thus a novel pathway for developing new drugs that reduce sickle polymerization and vaso-occlusion is under study.

Another consequence of sickle hemoglobin polymerization is hemolysis, and considerable evidence supports the notion that the most important consequence of hemolysis is vasoconstriction and vascular remodeling. This is due to impaired nitric oxide (NO) bioavailability, which appears to be the central feature of endothelial dysfunction [35]. There is resistance to replacement of NO by exogenous NO donors such as sodium nitroprusside and nitroglycerin, and this resistance is correlated with plasma hemoglobin levels [36]. Intravascular hemolysis releases hemoglobin and erythrocyte arginase into blood plasma, where the former scavenges NO, and the latter depletes plasma of L-arginine, the obligate substrate for NO synthase; together, these processes severely reduce NO bioavailability (Figure 72.2) [37]. Ordinarily, the gas exchange reaction of NO with oxyhemoglobin is inhibited by the diffusion constraints created by an

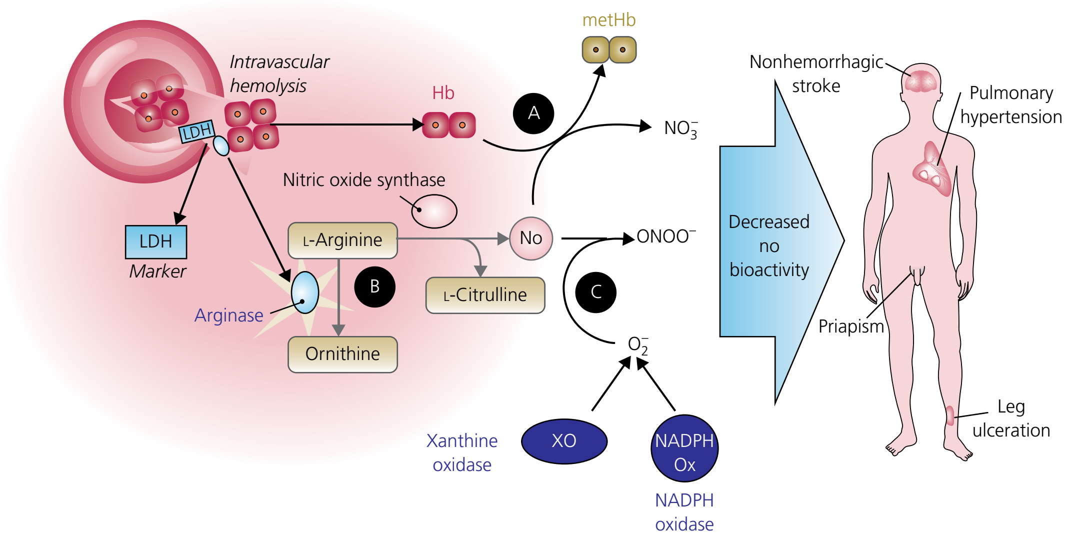

Figure 72.2 Intravascular hemolysis reduces nitric oxide bioactivity. Nitric oxide is produced by isoforms of nitric oxide (NO) synthase, using the substrate L-arginine. Intravascular hemolysis simultaneously releases hemoglobin, arginase, and lactate dehydrogenase (LDH) from red cells into blood plasma. Cell-free plasma hemoglobin stochiometrically inactivates NO, generating methemoglobin and inert nitrate (A). Plasma arginase consumes plasma L-arginine to ornithine, depleting its availability for NO production (B). LDH also released from the red cell into blood serum serves as a surrogate marker for the magnitude of hemoglobin and arginase release. NO is also consumed by reactions with reactive oxygen species produced by the high levels of xanthine oxidase activity and NADPH oxidase activity seen in sickle cell disease, producing oxygen radicals like peroxynitrite (ONOO-) (C). The resulting decreased NO bioactivity in sickle cell disease is associated with pulmonary hypertension and other clinical complications such as priapism. Source: Kato et al. 2007 [142]. Reproduced with permission of Elsevier.

intact RBC membrane. However, intravascular oxyhemoglobin abrogates this constraint and causes a 1000-fold increased rate of NO destruction [38]. An important consequence of this intravascular cascade is pulmonary hypertension, a clinical condition in adults with SCD that is associated with a 37% 6-year mortality in adults (see "Clinical description" later) [39]. The relationship of NO scavenging to vascular constriction and pulmonary hypertension has been questioned in vigorous commentary on this topic [40,41]. An opposing view is that pulmonary hypertension in SCD is rare and is a consequence of pulmonary embolization or in situ thrombosis that accompanies endothelial dysfunction and leukocyte activation in SCD. This argument was strengthened by clinical observations that hydroxyurea administration, which diminishes hemolysis, does not appear to protect from pulmonary hypertension [42], and in a trial of inhalational NO to replete blood levels that did not show an impact on the duration or severity of painful vaso-occlusive episodes [43].

Endothelin-1 is a potent pulmonary vasoconstrictor that acts as a counterpart to NO. Thus, in contrast to NO, its level is increased in pulmonary hypertension. It is also induced by hypoxia-induced factor-1α (HIF-1α), a factor that is expressed by endothelial cells under hypoxic conditions. A novel mechanism of HIF-1α induction and thereby endothelin-1 overexpression involves placental growth factor (PlGF), a recently discovered participant unique to sickle cell disease in particular and hemolytic anemias more generally [44]. PlGF is expressed in the marrow by erythroid cells and its expression helps drive the stress erythropoiesis of severe anemia. In a murine model of PlGF overexpression, endothelin-1 was induced and pulmonary hypertension was observed. In blood samples from 123 patients with SCD, PlGF levels were eightfold higher compared to healthy controls, and were associated with an elevated tricuspid regurgitation velocity (TRV). Thus it appears that NO depletion by hemolysis and other properties related to the exuberant erythropoietic response to severe anemia promote endothelin-1 overexpression and pulmonary hypertension in SCD.

Platelet activation is another important contributor to vaso-occlusion in SCD [45]. NO synthesized by the endothelium and platelets promotes vasodilation, but inhibits platelet activation, platelet aggregation, and endothelial adhesion in a normal vascular environment. However, this process is abrogated in SCD, in part because NO is depleted. Platelet activation is linked to hemolytic rate, suggesting that free hemoglobin may also trigger platelet activation by blocking the inhibitory effect of NO on platelet function [46]. Of interest, there appears to be an association between the severity of pulmonary hypertension and platelet activation, which then might help explain the underlying pathophysiology of this condition, which includes increased vascular tone, vascular proliferation, and *in situ* thrombosis, all of which may be precipitated by hemolysis-associated NO depletion [47]. A similar pathophysiology occurs in the cerebral arteries after stroke in SCD, which also includes intimal proliferation and arterial thrombosis. Thus, a common thread in the development of sickle vasculopathy has been suggested by these observations in disparate target organs, which is characterized by vasoconstriction, intimal proliferation with smooth muscle hyperplasia, and thrombosis *in situ*, even though the clinical manifestations of vascular injury in these organs remain quite distinct.

Clinical description

A comprehensive discussion of all the clinical complications of SCD is beyond the scope of this chapter; however, this brief description supports the notion that SCD is a serious, life-threatening hematologic disorder that significantly reduces the quality of life for most individuals and is associated with, on average, a 30-year decrement in life span [48]. These clinical observations provided the rationale to conduct clinical trials of HCT as a curative intervention for SCD, with the judgment that the risks inherent to HCT are balanced by the considerable difficulties of living with SCD.

Pain

The most common feature of SCD is pain, which varies by frequency and intensity both within and between individuals and sickle genotypes [49]. Febrile illnesses, dehydration, stress, and exposure to extreme temperatures can trigger a painful episode, but more typically an inciting cause is not apparent. Risk factors associated with frequent severe painful episodes, defined as ≥3 episodes per year that were observed in 20% of 381 children with SCD monitored prospectively, included older age, α-thalassemia trait, lowered LDH, and elevated TRV in a recent investigation [50]. Investigations of the frequency and severity of pain episodes by use of a daily diary have shifted perceptions about the spectrum of pain in SCD. The Pain in Sickle Cell Epidemiology Study (PiSCES) studied the longitudinal frequency of pain in a large cohort of adults who entered regular reports of pain in a daily diary for up to 6 months [51]. Patients experienced pain on 54.5% of days but reported an unplanned visit to a healthcare facility for pain treatment on 3.5% of days. Almost one third of patients had pain nearly every day. These observations, reported in children and adults, strongly suggest that painful episodes in patients with SCD occur frequently and are, for the most part, managed at home. These observations also strongly suggest that the clinical impact of pain is much broader than suggested by the Cooperative Study of Sickle Cell Disease (CSSCD), in which painful episodes, defined more narrowly as lasting longer than 2 hours and requiring clinical attention in a medical setting, occurred on average once annually in adults with HbSS, although a small group (5.2%) of individuals had more than 10 painful episodes per year. Thus, pain frequency, as measured by health utilization, vastly underestimates pain frequency and severity. A more accurate view is that painful episodes are frequent and can be characterized by a continuum of frequency and severity, with management at home in contrast to treatment in a healthcare facility at the extremes. Although the administration of hydroxyurea caused a statistically significant reduction in pain intensity and analgesic use, this effect was small (the proportion of days with analgesic use was 0.44 versus 0.40 in placebo and hydroxyurea groups, respectively; $p = 0.0006$) [52]. Thus, frequent painful episodes, particularly when unresponsive to supportive therapy, have been employed as an indication for HCT due to a significantly diminished quality of life.

Pulmonary complications

Acute chest syndrome and pulmonary hypertension

Pulmonary complications, including acute chest syndrome (ACS), pulmonary hypertension, and pulmonary fibrosis, conservatively have been linked as a cause of death in 20–30% of patients with SCD. The most frequent and clinically dramatic expression of pulmonary injury in SCD is ACS, a clinical triad of fever, chest pain, or other respiratory symptoms, and the appearance of a new radiographic infiltrate.

The etiology of ACS is multifactorial, but as often as not, an etiologic agent can be identified if rigorously pursued [53]. In childhood, most episodes are associated with infection, while in adults, ACS generally follows acute painful episodes. Secretory phospholipase A_2 is an enzyme that cleaves fatty acids, and this enzyme may be a biomarker for impending ACS [54]. The release of free fatty acids and the proinflammatory arachidonic acid in the lungs likely contributes to the pathogenesis of ACS, especially in cases of pulmonary fat embolism. Transfusions can prevent ACS when administered during a painful episode accompanied by an elevated serum secretory phospholipase A_2 level, although the feasibility of administering a therapeutic transfusion in a narrow time period based upon an elevated phospholipase A_2 level has been brought into question [55]. For purposes of prognosis, children who experience episodes of ACS early are more likely to experience recurrent episodes, which, if not associated with a higher risk of early mortality, certainly portend morbidity that makes interventions such as hydroxyurea and HCT worthy of consideration. In the long term, adult patients in the CSCCD who had recurrent episodes of ACS experienced restrictive pulmonary disease and abnormal diffusing capacity, which are the most frequent abnormalities noted on pulmonary function testing in affected adults [56]. Still, the global effect of SCD is expressed best in the finding that 90% of individuals had abnormal pulmonary function test results.

The prognostic importance of pulmonary hypertension (PH) as a serious complication of SCD has been established, although the frequency of this complication recently has come under scrutiny. However, as a screening tool to identify high-risk patients, several patient series have shown that adults screened by Doppler transthoracic echocardiography who have a tricuspid regurgitant jet velocity (TRV) that exceeds 2.5 m/s carry a high risk of sudden death. In three large screening studies, approximately 30% of patients had a TRV >2.5 m/s and 10% had a TRV >3 m/s. In all the epidemiologic studies performed to date, the risk ratio of early death in adults with a TRV >2.5 m/s ranged from 9.24- to 15.9-fold [57–59]. More recently, a larger cohort of 483 patients was screened in a study called the walk-PHASST ("walk" test for Pulmonary Hypertension and Sickle Cell Disease with Sildenafil Therapy) screening study [60,61]. In this cohort, the TRV ranged from 2.7 to 3 m/sec in 28.5% of the subjects and in 9.1%, the TRV was >3 m/sec. The 2-year mortality also was significantly increased in the patients with elevated TRV values ($p < 0.000006$). Together, these observations are very likely to help identify a subgroup of adult patients for whom HCT may provide a protective and curative effect in the long term, and for whom risk–benefit considerations are balanced.

Recently, the direct causality of pulmonary hypertension to risk of sudden death in SCD has been questioned as not all individuals with an elevated TRV also have pulmonary hypertension, which is classically defined by right heart catheterization as having a pulmonary arterial pressure of 25 mmHg. A much lower prevalence of PH was suggested by a large screening study in France, which evaluated patients with a TRV >2.5 m/sec by right heart catheterization [62]. The study observed that a minority of patients with elevated TRV (25%) also had a pulmonary arterial pressure >25 mmHg as measured directly by catheterization. Thus, more refined combinations of clinical risk factors for PH may be required to accurately identify those at highest risk of early mortality. PH is linked to elevated serum lactate dehydrogenase (released during hemolysis), and elevated N-terminal pro-B-type natriuretic peptide (NT-proBNP), a hormone that is released in response to cardiomyocyte stretch. As noted earlier, hemolysis appears to be mechanistically linked to PH, a notion that is supported by evidence that elevated serum lactate dehydrogenase also is associated with a high risk of early mortality in adults with SCD. Similarly, a study of banked samples from the CSSCD that analyzed the frequency of NT-proBNP levels >160 pg/mL observed elevated levels in 26% of adults, and high levels were also associated with markers of hemolysis that included elevated LDH, low hemoglobin, and elevated serum bilirubin [63]. An NT-proBNP level >160 pg/mL was an independent risk factor of early mortality (RR 6.24; 95% CI 2.9–13.3; $p < 0.0001$). Applying more stringent clinical criteria that included TRV ≥2.8 m/s, a 6-minute walk distance <500 m, and unexplained dyspnea or oxygen desaturation, 65% of 86 patients who fulfilled these criteria had PH by right heart catheterization [39]. Thus, it is very likely that further refinement of these clinical and laboratory screening tools will enable better accuracy of identifying individuals at high risk for PH and who might benefit from HCT. This is critical because interventions that include sildenafil [60] and bosentan [64] have not improved outcomes in SCD patients with PH.

Stroke

The consequence of vaso-occlusion in cerebral arteries is stroke, a leading cause of morbidity and disability in SCD. The risk of stroke in children with SCD in increased by more than 300-fold, making SCD the most common cause of childhood stroke [65]. The majority of strokes occur in patients with homozygous HbS, and many fewer occur in other SCD genotypes. Clinically overt stroke was observed in 11% of SCD patients by 20 years of age, while 27% had subclinical evidence of "silent" cerebral infarction on brain magnetic resonance imaging (MRI) by age 6 and 37% by age 14, which is defined as a radiographic abnormality that is not associated with neurologic symptoms or a clinical event [66,67]. These injuries are associated with poorer global intellectual functioning. Recently, a cross-sectional study in 652 children with SCD evaluated the frequency of acute silent ischemic events and observed an incidence of 47.3 events per 100 patient-years [68]. While these events are potentially transient, the events are chronic and intermittent, suggesting a continuous risk of brain ischemia and functional impairment.

Co-inherited α-thalassemia appears to confer protection from stroke by possibly improving RBC deformability and decreasing hemolysis [69]. There is also increasing recognition about immune regulation and inflammation with regard to human leukocyte antigen (HLA) genes in diseases such as atherosclerosis and aortic aneurysm [70]. There is a predisposition to Moyamoya disease among Japanese children who inherit the class II HLA allele DQB1*0502 [71]. There was also a strong association with stroke in SCD children who inherited this allele [72]. Likewise, unique HLA alleles DPB1*0401 and DPB1*1701 were associated with increased susceptibility to and protection from small cerebral vessel stroke, respectively.

A number of other candidate genes have been studied by epidemiologic methodologies to assess their association with stroke. Recently, a report of elevated levels of platelet-derived growth factor and brain-derived neurotropic factor were observed in children with elevated cerebral blood flow and stroke, suggesting an association [73]. Vascular cell adhesion molecule-1 (VCAM-*1)*, a gene responsible for expression of adhesion molecules regulating the attachment and migration of leukocytes, is upregulated in response to sickle erythrocytes and appears to be involved in the pathophysiology of SCD-related microvascular occlusion [32]. The VCAM-1 (−1594) *C* variant was associated exclusively with small-vessel stroke risk in a cohort from the CSSCD [74]. Other single-nucleotide polymorphisms in linkage disequilibrium may be present at this locus and suggest a stroke "haplotype" [75]. Further evaluation and confirmation in larger prospective studies is required to document their utilization as a predictor of stroke risk in SCD. However, these may offer utility also in screening those who might benefit from HCT before the onset of central nervous system injury.

Therapeutic alternatives to HCT

RBC transfusions and stroke prevention

It is possible to determine the risk for clinical stroke in children with SCD by measuring the flow velocity in the intracranial arteries by a non-invasive method termed transcranial Doppler ultrasonography (TCD) [76]. The risk of stroke is increased when the time-averaged mean of the maximum (TAMM) flow velocity in the distal internal carotid artery or middle cerebral artery (MCA) exceeds a threshold observed in stenosis. The association of increasing TCD TAMM velocity and increasing risk for stroke formed the basis of the primary stroke prevention trial, the Stroke Prevention Trial in Sickle Cell Anemia (STOP) [77]. The STOP trial tested the hypothesis that periodic blood transfusions would lower the risk of stroke compared with the risk while receiving standard care. The STOP trial was halted prematurely when 11 strokes were observed in the standard supportive care arm and only one in the transfusion arm, indicating a 92% relative risk reduction over 2 years of follow-up on stroke risk with chronic transfusion therapy.

To extend these findings, the STOP investigators conducted a second randomized, controlled trial, the Optimizing Primary Stroke Prevention in Sickle Cell Anemia (STOP 2) trial, to determine whether it was possible to limit the duration of transfusion prophylaxis [78]. Children whose Doppler studies normalized after 30 or more months of transfusion in the STOP trial were eligible for enrollment in STOP 2, and were randomized to halt or to continue regular RBC transfusions. Among the 41 children in the transfusion-halted group, high-risk Doppler findings developed in 14 and stroke in two others by a mean duration of 4.5 (standard deviation ± 2.6; range 2.1–10.1) months after the last transfusion. Neither of these events occurred in the 38 children who continued to receive transfusions, so this trial was terminated early. The authors concluded that discontinuation of transfusion for the prevention of stroke in high-risk children with SCD results in a high rate of reversion to abnormal blood flow velocities on TCD and stroke. These conclusions were supported by extended follow-up observations that included additional strokes in six children during the post-trial follow-up period [79]. In addition, the effect of stopping transfusions on developing new or progressive silent cerebral infarctions by MRI was also determined. At the end of the study, 3 of 37 (9.1%) children developed a new brain MRI lesion in the group treated by transfusions, while 11 of 40 (27.5%) in the group that halted transfusions had new lesions [80]. In addition, there was no change in the total number of MRI brain lesions in the transfusion group, while the number of lesions increased from 27 to 45 in the group that halted transfusions. Thus, regular transfusion therapy also protected from subclinical ischemic brain injury.

It is unclear how long transfusion therapy should be continued as a means of preventing stroke in children with SCD, a question that was not formally resolved by the STOP 2 trial. A trial similar in design to the STOP study has completed accrual to determine whether transfusion is warranted on the basis of MRI lesions in clinically asymptomatic children with SCD, was recently published, and showed that regular RBC transfusions significantly reduced the incidence of cerebral infarct recurrence [82]. Among children who develop a clinical stroke, the risk of a second stroke is at least 20%, even with regular transfusion therapy. In a recent prospective study of 40 patients from seven academic centers with stroke who had regular brain MRI imaging performed over 2 years, the rate of a second stroke or a transient ischemic attack was 40% and new or enlarging cerebral infarcts were observed in 45% of patients [83]. Together, these trials have defined a subgroup of children with SCD who appear to benefit from prevention of neurologic injury by receiving regular RBC transfusions. Thus, like those who have stroke, those at risk for stroke and other brain injury are very likely also to be suitable candidates for HCT, as an alternative to long-term RBC transfusions.

Hydroxyurea

Hydroxyurea is a potent inhibitor of ribonucleotide reductase, which also stimulates fetal hemoglobin production, which in turn inhibits the formation of the sickle hemoglobin polymer. The laboratory effect of hydroxyurea in SCD is to raise the HbF fraction, serum hemoglobin, and the red cell mean corpuscular volume [10,84]. Hydroxyurea also decreases the white blood cell, reticulocyte, and platelet counts while increasing NO production [85], decreasing RBC intracellular dehydration, and decreasing red cell adhesiveness to endothelium. Together, these laboratory effects translate into a clinical benefit of decreased rates of pain and ACS events in severely affected adults and children [10,84]. A long-term follow-up of the Multicenter Study of Hydroxyurea (MSH) showed that, at 17.5 years, while 43% of the original cohort had died, the mortality rates among patients who took hydroxyurea continuously for 10 to 15 years compared to those treated less than 5 years were 6.77 and 1.78 per 100-person years, respectively [10]. A clinical benefit also was observed in a pediatric randomized placebo-controlled trial of hydroxyurea (BABY-HUG) in which the pain rate was nearly halved and the rate of dactylitis was reduced fivefold in the hydroxyurea group, with marginally fewer hospitalizations and RBC transfusions as well [86]. Of interest, there was no significant benefit in protection from progressive splenic and renal injury observed in the hydroxyurea group, suggesting that ongoing subclinical vaso-occlusion was not prevented by regular HU use in young children. Nonetheless, the ready availability of hydroxyurea therapy and its favorable safety profile make it an appropriate intervention in most children and adults.

Unfortunately, the beneficial effect of hydroxyurea is neither universal nor curative, as adult patients with SCD die of disease complications while receiving hydroxyurea therapy [10]. In addition, 81 of 225 children in one series had hydroxyurea therapy withdrawn, primarily due to a lack of clinical response or difficulty with adherence, although there were also failures due to stroke ($n = 2$) and the development of a TCD velocity greater than 200 cm/s ($n = 3$) [87]. Investigation of the quality of life showed that hydroxyurea improved some measures of quality of life, including general health perception and pain recall [88]. However, there was no effect of hydroxyurea on other quality of life measures such as physical functioning or physical role. Even though many experienced an average 50% reduction in acute pain episodes, subjects still had frequent acute pain episodes and high levels of chronic pain. Thus, while hydroxyurea is the sole Food and Drug Administration-approved drug for SCD and its use when indicated should be applied more broadly, it does not appear to be a substitute for the curative potential offered by HCT.

To expand the indications for hydroxyurea, prospective studies have focused on the efficacy of hydroxyurea therapy on recurrent stroke risk and on TCD velocities in children with SCD. The effect of hydroxyurea on hemoglobin levels also makes it feasible to conduct phlebotomy to reduce iron overload in patients who have received chronic transfusions to prevent stroke. In one series of 35 patients, secondary stroke prevention and the reduction of iron stores was facilitated by hydroxyurea, although seven patients experienced a second infarctive stroke after transfusions were replaced by hydroxyurea [89]. In another study, after a minimum period of 6 months for stroke prevention by regular transfusions, hydroxyurea reduced the rate of recurrent stroke in children and young adults to 4.6 per 100 patient-years, a rate which is significantly lower compared to untransfused patients [90]. However, the randomized Stroke Without Transfusions Changing to Hydroxyurea (SWiTCH) trial showed that children with stroke treated by hydroxyurea alone had a higher rate of second stroke compared to those managed with regular RBC transfusions (7/67 vs. 0/66, respectively) [91]. While hydroxyurea may reduce the recurrent stroke risk compared to no transfusion therapy, as demonstrated in a large Jamaican cohort [92], it is an inferior method for preventing second stroke compared to regular transfusion therapy and maintaining the HbS fraction <30%.

Table 72.2 Indications of hematopoietic cell transplantation for sickle cell disease

- Patients with sickle cell disease (HbSS or HbSβ^0-thalassemia) less than 16 years of age
- One or more of the following complications:
  - Stroke or central nervous system event lasting longer than 24 hours
  - Impaired neuropsychologic function with abnormal cerebral magnetic resonance imaging and angiography
  - Recurrent acute chest syndrome
  - Stage I or II sickle lung disease
  - Recurrent vaso-occlusive painful episodes or recurrent priapism
  - Sickle nephropathy (glomerular filtration rate 30–50% of predicted normal)
- Other indications to consider:
  - Abnormal transcranial Doppler scan
  - Pulmonary hypertension
  - Silent cerebral infarction

HCT for SCD

Current indications for HCT

In standard practice, HCT for SCD currently is reserved almost exclusively for patients with clinical features that portend a poor outcome or significant sickle-related morbidity, in part due to the toxicity of this intensive therapy. These clinical indications, which were adapted from the multicenter investigation of bone marrow transplantation for SCD, are listed in Table 72.2 [93]. In addition, these criteria have been applied almost exclusively to children, where the risk–benefit ratio is most advantageous in terms of years of life gained among those who survive with sustained engraftment of donor cells. This is evolving, however, as reduced toxicity regimens become established and a larger proportion of children survive to young adulthood where supportive care measures are limited and the risk of sudden death is high. In a small patient series from France that included 15 adults who received myeloablative conditioning regimens, an event-free survival of 93% was observed [94]. For all patients, clinicians must carefully weigh therapeutic alternatives to HCT, with particular attention to safety, efficacy, availability, and the cost of intervention [95,96].

Current results of HCT for SCD

The worldwide experience of transplantation for SCD is summarized in Table 72.3 [93,97–110] and there are approximately 400 published cases. In the collective experiences of these studies, the transition of HCT from an experimental intervention reserved for severely affected patients, to one in which younger children with early signs of sickle-related morbidity are targeted, has been observed. Several series in Europe and North America have reported very similar results after HLA-identical sibling transplantation in which bone marrow is the source of hematopoietic cells [104–106,111]. There have been no randomized trials performed comparing HCT to supportive care such as hydroxyurea. The principal aim of these multicenter phase I–II clinical studies was to define more completely the risks and benefits of this therapy, and to characterize the natural history of those surviving free of SCD. The results of transplantation were best when performed in children with SCD who had HLA-identical sibling donors. Even though many children who received allografts had significant sickle-related complications such as stroke and recurrent episodes of ACS, the disease-free survival varied from 80–85% in several series. In the most recent series, the disease-free survival has improved to approximately 90% (Table 72.3) [97–99]. However, 5–10% of patients died of complications related to transplantation, with graft-versus-host disease (GVHD) and its treatment as the leading cause of death. Most clinical investigations of HCT for SCD have targeted enrollment of children *in lieu* of adults, but the experience of HCT in adults with SCD is growing [94,100,103].

In the multicenter investigation of HCT for SCD, 59 children who ranged in age between 3.3 and 15.9 (median 9.9) years received HLA-identical sibling marrow allografts between September 1991 and April 2000 [112]. Patients received a myeloablative combination of busulfan (BU), cyclophosphamide, and equine antithymocyte globulin (ATG), and most received a combination of methotrexate and cyclosporine after HCT to prevent GVHD. Fifty of 59 children survive disease-free after HCT. The Kaplan–Meier probabilities of survival and disease-free survival are 93% and 85%, respectively (Figure 72.3). A publication from the Center for International Blood and Marrow Transplantation Research reported very similar results. Outcomes after HLA-matched sibling HCT in 67 patients with SCD transplanted between 1989 and 2002 were described [105]. Rates of acute and chronic GVHD were 10% and 22%, respectively. Sixty-four of 67 patients are alive; 5-year probabilities of disease-free and overall survival are 85% and 97%, respectively.

There were several patient series of HCT for SCD in Europe conducted in parallel. Results among 101 patients who received conventional myeloablative HLA-identical sibling HCT in Europe were remarkably similar to North American reports, with an overall survival probability of 88% and disease-free survival of 80% [104]. A French report included 87 consecutive patients treated between November 1988 and December 2004 at 14 centers [110]. The median age was 9.5 years, and the leading indication for HCT was stroke or transient ischemic attack (*n* = 36) and the development of abnormal cerebral arterial flow velocity as detected by TCD (*n* = 8). Five of the 18 patients who did not receive ATG had graft rejection. The rate of graft rejection declined from 22.6% to 2.9% after the addition of ATG to the conditioning regimen (Figure 72.4(a)). The Kaplan–Meier estimate of event-free survival at 5 years was 86.1%. Multivariate analysis showed that the date of transplantation was the only significant risk factor. The 5-year event-free survival rate was 95.3% in patients treated after January 2000, compared with 76.7% in patients treated earlier (Figure 72.4(b)). A recent series of 11 patients treated at a single center in Rome between 2004 and 2009 reported a disease-free survival rate of 90% after HLA-ID sibling bone marrow transplantation [97].

A retrospective review of 24 Belgian patients with SCD analyzed the impact of pretransplant ATG and hydroxyurea on outcome [113].

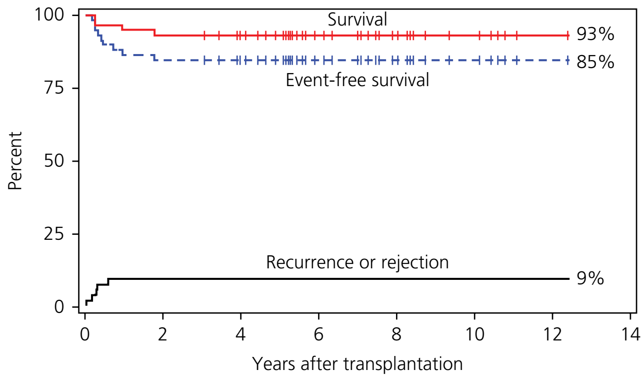

Figure 72.3 Survival probabilities and the cumulative incidence of graft rejection after BMT for sickle cell disease. Kaplan–Meier probabilities for survival and EFS after BMT for SCD are shown. An event was defined as death, graft rejection, or return of SCD. A cumulative incidence curve for graft rejection/disease recurrence is also depicted. Source: Walters et al. 2010 [112]. Reproduced with permission of Elsevier.

The administration of hydroxyurea before HCT was associated with a significantly lower rate of graft rejection, compared with patients who did not receive hydroxyurea, but the administration of ATG before transplantation did not affect the rate of engraftment. Overall 20 of 24 patients had stable engraftment of donor cells after HCT, but none of those who received hydroxyurea before transplantation with ATG in the conditioning regimen had graft rejection or a late recurrence of SCD. This suggests that the augmentation of pretransplantation immunosuppression might be necessary to overcome the immunologic barrier of tolerance to donor histocompatibility antigens. The propensity for graft rejection even after HLA-identical sibling HCT follows the hypothesis that multiple transfusion exposures before HCT induce sensitization to minor histocompatibility antigens expressed on the surface of transfused cells. It appears possible that leukocytes present in blood products are not alone in this ability to cause sensitization, as RBCs may also present histocompatibility antigens via the HLA class I pathway to elicit expansion and activation of host CD8$^+$ T cells [114].

Stable donor–host chimerism after high-dose HCT for SCD

The observation of donor–host hematopoietic chimerism after conventional high-dose HCT has lent substantial support to the notion that persistence of even a fraction of normal erythropoiesis may elicit a curative clinical effect [108,115]. The basis of this effect appears to be twofold: improved survival of healthy donor erythrocytes in the blood compared with sickle erythrocytes, and ineffective erythropoiesis in the SCD marrow that lends a survival advantage to donor erythroid progenitors [116,117]. Approximately 25% of children with SCD developed stable mixed chimerism after HLA-identical sibling HCT [111,112].

In the multicenter investigation of bone marrow transplant for SCD, 13 of 50 patients with clinically successful allografts developed stable mixed chimerism, which is defined as the durable coexistence of donor and host hematopoietic cells well after the discontinuation

of postgrafting suppression. The level of donor chimerism, measured in peripheral blood 6 or more months after transplantation, varied between 90% and 99% in eight patients who had normal hemoglobin levels, with a lower proportion of donor cells (range 11–74%) in five. Among these five, hemoglobin levels varied between 11.2 and 14.2 (median 11.3, mean 12.0) g/dL. None of the patients experienced painful events or other clinical complications related to SCD after HCT. One patient, who had a stroke before transplantation, had no further strokes after HCT and had stable appearance by cerebral MRI, despite having as few as 10% donor cells detectable in the peripheral blood.

In the French series, low levels of residual host hematopoiesis were observed significantly more frequently in patients who did not receive ATG before HCT ($p = 0.04$ at 12 months and $p = 0.002$ at 24 months post-transplant) [111]. A higher fraction of residual host cells was observed in patients who received ATG ($p = 0.03$ at 12 months and $p = 0.001$ at 24 months post-transplant), and this level of donor–host chimerism remained stable in the long term. These observations are consistent with the idea that chimerism, even with a minority of donor cells, can have a significant ameliorative effect so that full engraftment of donor cells is not a requirement for successful HCT, and that the donor chimerism fraction remains stable 12 months and longer after HCT.

Reduced-intensity HCT for SCD

Due in part to the observations discussed earlier, it was reasoned that conditioning therapy might be adjusted to promote stable engraftment of a threshold fraction of donor cells that would be sufficient to prevent vaso-occlusion, and that this regimen could be carried out more safely than conventional high-dose conditioning, particularly in adult patients. Toward this end, several groups have attempted to apply reduced-intensity HCT to SCD, utilizing conditioning regimens of varying intensity [100,107,108,117]. A minimally toxic regimen was first developed in a large animal model and translated successfully into human trials for older adult patients with hematologic malignancies [108]. When applied to SCD, this approach was safe, generated little or no acute GVHD, and in most cases was associated with an initial period of donor engraftment. Unfortunately, in nearly all cases, withdrawal of postgrafting immunosuppression was followed by graft rejection with disease recurrence (Table 72.4). This approach was modified by a group of investigators at the National Institutes of Health that resulted in engraftment of donor cells in the majority of adults with severe disease after long-term administration of sirolimus for postgrafting immunosuppression [100]. Mixed donor–host hematopoietic chimerism was established in 9 of 10 patients who had significant medical comorbidities after HLA-identical sibling mobilized peripheral blood stem cell transplantation. The patients were prepared for HCT with a non-myeloablative combination of alemtuzumab, fludarabine, and total body irradiation, 300 cGy. The mixed chimerism was sufficient to decrease markers of hemolysis (reticulocyte count, total bilirubin and LDH levels) and the hemoglobin levels gradually improved after HCT without RBC transfusions (Figure 72.5). More recently updated results indicate that 23 patients now survive after HCT and that 5 of 17 patients had >50% donor T-cell chimerism and sirolimus was successfully discontinued [118]. In another patient series of reduced-intensity HCT, there was a twofold higher expression of donor β-globin RNA

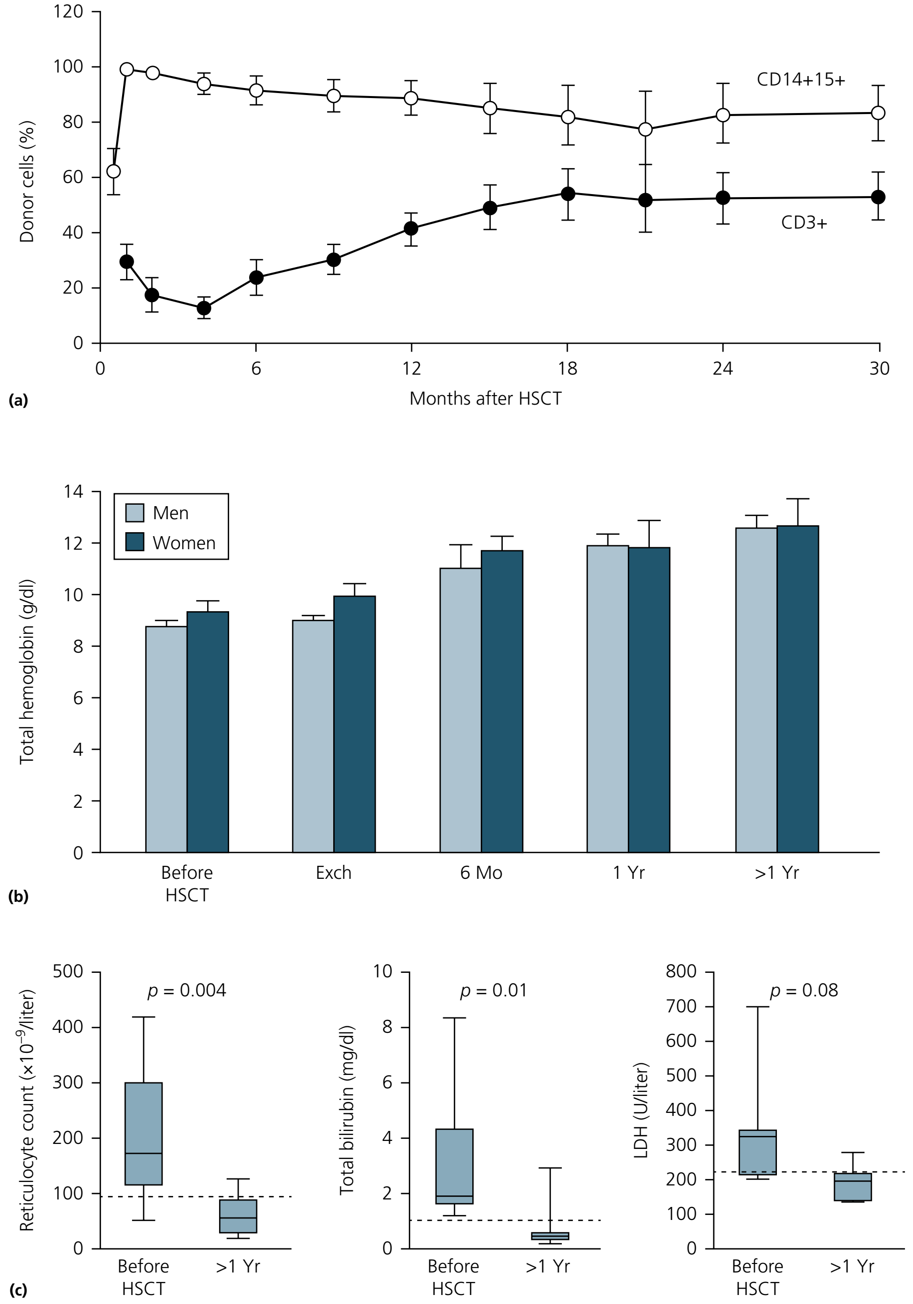

Figure 72.5 Donor cell chimerism and laboratory measurements after hematopoietic stem cell transplantation. (a) shows the mean donor chimerism among $CD3^+$ T cells and $CD14^+15^+$ myeloid cells after HCT. compared with total genomic DNA in the blood after non-myeloablative HCT. Direct bone marrow analysis revealed ineffective erythropoiesis of native HbSS erythroblasts, with a progressive increase in representation of donor RBCs during erythrocyte maturation [117]. These findings were associated with clinical benefit after transplantation, and with improvements in hemolysis, endothelial function, and NO bioavailability; however, they did not persist after graft rejection.

An increasing number of patients have received regimens that are less intense than a high-dose regimen, but retain a moderate degree of the myelosuppressive effect in order to suppress the host-versus-graft reaction and promote engraftment. These regimens require hospitalization, but their risk of regimen-related toxicity is related to the profound immunosuppression of the regimens and an accompanying risk of opportunistic infection (Table 72.4). Donor chimerism was successfully established in children who received a reduced-intensity regimen consisting of BU, fludarabine, ATG, and total lymphoid irradiation (500 cGy) [109]. Seven patients who were between 6 and 18 years of age received HLA-identical sibling bone marrow transplantation with cyclosporine and mycophenolate mofetil for postgrafting immunosuppression. Treatment-related toxicity was minimal, and all the patients had evidence of stable donor engraftment. Another study that included 16 children with non-malignant disorders included one patient with SCD [119].

The patients received melphalan, fludarabine, and alemtuzumab before transplantation, and included seven patients who received unrelated or HLA-mismatched related donor allografts. Twelve of the 16 (75%) patients survive disease-free after transplantation, and none of the surviving patients had graft rejection. This particular approach is being studied in a multicenter clinical trial of unrelated donor HCT for children with symptomatic SCD in the United States (Sickle Cell UnRelated donor Transplant study, SCURT), and the results after unrelated donor umbilical cord blood transplantation recently were reported (see later).

Effect of donor hematopoiesis on vaso-occlusion

After successful HCT for SCD, patients with stable engraftment of donor cells have not experienced clinical complications or required transfusions, even when there was stable mixed donor–host hematopoietic chimerism [111,112]. In addition, investigators have reported improvements in splenic function and osteonecrosis [120,121]. Patients treated by HCT also had stabilization of the underlying cerebral vascular disease. Forty-six of 55 patients who were enrolled in the multicenter study had a cerebral MRI performed a median of 25.4 months after transplantation [112]. These studies were compared with pretransplantation baseline examinations in all but four patients. Surviving patients with stroke who also had stable engraftment of donor cells ($n = 25$) experienced no subsequent stroke events after BMT. However, patients who had graft rejection after BMT were not protected from stroke. One patient with graft rejection experienced a second stroke when the HbS fraction reached 60% after BMT and another patient with graft rejection had a subarachnoid hemorrhage after BMT. In total, 28 of 29 (97%) patients with stroke survived after transplantation, and 26 of 29 (90%) survived stroke-free after BMT. Ten patients had evidence of silent cerebral infarction before transplantation. Of these 10, eight patients had post-BMT studies performed a median of 1.7 (range: 0.5–4.9) years after BMT, which were stable in three patients and four patients had lesions that had evolved to a smaller size by brain MRI. There were no clinical strokes after HCT in this group. Sixteen patients had no documented CNS disease before BMT. All 10 studied in this group had normal MRI appearance a median of 3.1 (range: 0.5–5.2 years) after BMT. Together, these observations show that most patients had stabilization of cerebral vasculopathy after HCT (Table 72.4). These data also suggest that, in those with silent cerebral infarction who are at risk to develop stroke, there is protection from disease progression and a first stroke.

A similar experience was reported from the French group [111]. Among the 36 patients with a history of stroke before HCT, two had a recurrent stroke. One patient experienced a transient ischemic attack 10 days after HCT, while the other, who had severe cerebrovascular injury with Moyamoya disease, had a fatal intracranial hemorrhage 32 days after HCT. With a median follow-up of 6 years, the risk of recurrent stroke was 5.6%, which mirrors the rate of second stroke observed in SCD patients treated by regular RBC transfusion therapy after a first stroke. However, vascular occlusions tended to persist after HCT, and the long-term outcome varied somewhat: in five, the stenoses resolved, in 16 there was no change, and in two cases, the stenoses showed progression. However, none of the patients with durable donor engraftment had a clinical stroke or silent ischemic lesion, including the two patients who had progressive cerebrovascular narrowing. Cortical atrophy worsened in two cases. In addition, cerebral artery velocity was significantly decreased ($p < 0.001$) by 1 year after HCT in the 49 patients who had a pre-HCT TCD examination performed [the TCD velocity declining from 138 (range 88–188) before HCT to 100 (range 66–134) cm/s as measured in the right MCA, and from 138 (range 92–184) to 103 (range 63–143) cm/s as measured in the left MCA]. The TCD velocity also normalized by 3 months after HCT in two patients who had abnormal measurements before HCT, even though both had been treated by regular RBC transfusions before HCT.

In other series, patients with stroke before HCT have also experienced transient ischemic attacks and intracranial hemorrhage in the era before measures to prevent these adverse events were instituted [122,123]. After the institution of preventive measures, neurologic complications still occurred after transplantation, but these tended to be self-limited events such as seizures with no long-term sequelae. One group of investigators observed radiographic progression in some patients with SCD who underwent HCT for stroke [124]. Five of nine patients had either new or slightly increased size of cerebral lacunae or leukoencephaly that stabilized 2–7.5 years after HCT. Thus, it is possible that these observations reflect the evolution of cerebrovascular disease that existed before bone marrow transplantation. Of interest, these cerebral MRI changes were not associated with progressive neurocognitive deficits.

Pulmonary function also was evaluated systematically after HCT in the multicenter collaborative study. Eighty-two percent of the surviving patients had pulmonary function measured a median of 3.2 years after HCT. The mean predicted FEV1 changed from 88% ± 10% to 86% ± 11% ($p = 0.59$) and the mean predicted FVC changed from 78% ± 16% to 81% ± 12% ($p = 0.45$) after transplantation. Before HCT, 11 had restrictive changes, 2 had obstructive changes, and 10 patients had normal lung function at baseline. Compared to pre-HCT measurements, the RV ($p = 0.02$) and RV/TLC ($p = 0.03$) were significantly decreased after BMT. The observed difference in RV and in RV/TLC suggested that there was decreased air trapping and therefore improved lung function after BMT. Overall, patients who had normal baseline pulmonary function were likely to remain normal (8 of 10) after BMT. Patients who had restrictive disease at baseline were likely to have improved or persistent, but not progressive restrictive disease (10 of 11). Taken together, these data show that most patients had stable pulmonary function after BMT. These results contrast with the natural history of SCD, for which there is growing evidence to indicate that the pulmonary toxicity of SCD is progressive, and may be expressed as either restrictive or obstructive pulmonary disease [125,126]. In a series from the Cooperative Study of Sickle Cell disease, only 10% of adults had normal PFT results, with restrictive pulmonary disease (74%) accounting for the most frequent abnormality among 310 adult SCD individuals tested [127].

Growth and development after HCT for SCD

There remains concern about possible growth impairment after HCT for SCD. The potential for growth impairment stems, in part, from the gonadal toxicity associated with high doses of BU, particularly in females. A report compared four groups of children with SCD in an analysis of growth after HCT. Children who were enrolled in the CSSCD study comprised one supportive therapy comparison group. Children who were enrolled in the HUG-KIDS trial made up the remaining two comparison groups [128]. These two groups included children who had pretreatment growth measurements (HUG-KIDS Pre) and the same children who again had measurements for at least 1 year after achieving the maximum tolerated dose of hydroxyurea (HUG-KIDS HU).

Using two-level hierarchical linear models, there were no statistically significant differences in the estimated height (weight) velocity curves between the HCT and the three comparison groups among females; however, there were significant differences between males in the HCT and CSSCD groups The predicted height velocity during follow-up in the HCT group was greater than the velocity in the CSSCD group between 3.3 years and 11.6 years of age. After this period of 8.4 years, there was no apparent growth benefit associated with HCT. As a result, the predicted height velocity in HCT males who were greater than 12 years of age at transplantation was less than the velocity in CSSCD males. Similarly, until the baseline age of 12.1 years, the linear weight velocity in the HCT group was greater than in the CSSCD group. In summary, growth after transplantation for SCD was not impaired, except in older males. These data show that conventional high-dose HCT generally had no adverse effect on height or weight gain in young children.

Gonadotropin and sex hormone levels of surviving patients have also been monitored, and these confirm the toxic effect of BU on gonadal function. In the multicenter study, the median ages at evaluation were 21.6 (range: 16.1–28.5 years) and 21.7 (range: 14.1–27.8 years) among the males and females, respectively. Among these, 13 males (39%) and 14 females (64%) had post-transplantation endocrine studies reported. Eight of 14 females had increased gonadotropin levels and/or below normal estradiol levels, a finding consistent with primary ovarian failure in the majority of postpubertal females. Only 4 of 14 females had normal estradiol levels. However, one female had a successful pregnancy 13 years after BMT and another female with graft rejection gave birth to a healthy baby following preimplantation genetic diagnosis 14 years after BMT, although she had experienced two previous spontaneous abortions several years earlier. Among six evaluable prepubertal girls in the Belgian cohort, five had primary amenorrhea with elevated serum LH and FSH [104]. Two postpubertal females developed secondary amenorrhea.

In the French series, seven postpubertal females (ranging from 13 to 22 years of age) developed amenorrhea after HCT with decreased serum estradiol and elevated LH and FSH levels, and received hormone replacement therapy [111]. In addition, most females who were prepubertal before HCT received hormone replacement therapy to promote the development of secondary sexual characteristics after they reached a bone age of 13 years. However, two younger girls (6.4 and 8.3 years of age) experienced spontaneous pubertal development, raising the possibility that HCT performed in very young patients might not be associated with delayed puberty. Nonetheless, it is anticipated that many if not most of the females will require hormonal replacement therapy after HCT with high-dose BU.

Males may be somewhat more resistant to the adverse effect on gonadal function, although the long-term outcome remains somewhat uncertain. Of seven males from the multicenter study of HCT for SCD the LH and FSH levels were normal and less than normal in four after transplantation. However, only three of 13 had normal testosterone levels, consistent with hypogonadotrophic hypogonadism in most of the pubertal males [112]. Testicular function was also adversely affected in four of six evaluable boys from the Belgian cohort who demonstrated decreased testosterone and elevated FSH levels [104]. However, all the male recipients from the French series had testosterone, FSH, and LH levels in keeping with their bone age and pubertal status [111]. Six Belgian males, five of whom were prepubertal before HCT, had semen analysis performed 14 – 21 years HCT and preparation with BU/CY or BU/CY with total lymphoid irradiation (TLI). The three TLI recipients had azoospermia while two of the three remaining patients were azoospermic and one patient was normal [129]. While none of these series has definitive information about the impact of treatment on fertility, there is an expectation, particularly among postpubertal females that fertility is likely to be adversely affected after myeloablative BU. The possibility of ovarian tissue autografting after myeloablative HCT for SCD was recently reported, however, and may offer an alternative in the future [130].

Delays in growth and development after HCT are amplified by iron overload, illustrated best in children with thalassemia major who have significant transfusional iron loading before HCT [131]. The transfusion iron burden in SCD can approach that observed in thalassemia major, thus a strategy to eliminate iron after successful HCT is warranted [132]. Phlebotomy after HCT is a safe and effective method for reducing iron stores, and should be pursued in patients with SCD who have iron overload [133]. Treatment by iron chelation therapy is an alternative in those who cannot support regular phlebotomy [134].

Alternative sources of donor hematopoietic cells

The use of umbilical cord blood (UCB) *in lieu* of bone marrow in transplantation for SCD is of interest, due primarily to a lowered risk of GVHD after UCB transplantation. However, this benefit is balanced by a higher rate of graft rejection and a longer duration until hematologic recovery that accompanies UCB transplantation. Thus, to overcome these risks, investigators have modulated pre- and postgrafting immunosuppression and intensified supportive care to ensure favorable outcomes.

In a report of 44 patients that included 11 with SCD who received HLA-identical or one-antigen HLA-mismatched sibling UCB allografts, the overall 2-year SCD-free survival rate was 91%, with one patient experiencing recurrent disease [135]. However, among patients who received thiotepa or fludarabine in addition to the BU/CY backbone and who did not receive methotrexate with postgrafting immunosuppression, the outcome after sibling donor UCB transplantation was superior, particularly among recipients with thalassemia major. In addition, only four of 44 patients experienced acute, and two chronic, GVHD after UCB transplantation, and there were no deaths related to GVHD. This experience was expanded in a larger, more recent comparison of outcomes after UCB and marrow transplantation from HLA-ID sibling donors involving 485 patients with SCD or thalassemia [136]. The overall 6-year disease-free survival in 160 patients with SCD who were treated between 1994 and 2005 by either source of hematopoietic cells was 92 ± 2%. The disease-free survival after UCB transplantation was 90 ± 5% in 30 patients and it was 92 ± 2% after bone marrow transplantation in 130 patients. In this investigation, the outcome after UCB transplantation also was influenced by the use of methotrexate for GVHD prophylaxis, which was a significant variable in a multivariate analysis of factors influencing the probability of disease-free survival (HR 3.81; $p = 0.004$). None of the patients developed chronic extensive GVHD and none of the patients died of GVHD after UCB transplantation. Thus, while it appears that UCB and marrow from HLA-ID donors might be used interchangeably to support HCT for SCD, the use of UCB extends a benefit in terms of a lower risk of acute and chronic GVHD.

The current experience of unrelated donor UCB transplantation for SCD is quite limited, but it illustrates the challenges yet to be overcome. In an analysis by the CIBMTR that included patients with thalassemia and SCD, 16 children had SCD [102]. Nine of 16

SCD patients received myeloablative conditioning. Seven of 16 patients achieved neutrophil recovery a median of 22 days after transplantation with full donor chimerism. Eight of 16 patients were alive and disease-free with an overall survival probability of 62 ± 9%. In multivariate analysis, disease-free survival was higher if the UCB unit contained $>5 \times 10^7$ TNC/kg recipient weight (HR 0.4; $p = 0.01$). The cumulative incidence of chronic GVHD in all patients was 16 ± 4%. Finally, enrollment in the UCB arm of the SCURT trial in the United States was stopped early due to a high-rate of graft rejection following a reduced-intensity regimen of alemtuzumab, fludarabine, and melphalan [101]. Eight children received UCB from unrelated donors matched at 5 or 6 of 6 HLA antigens. Five patients experienced autologous marrow recovery after UCB transplantation and one died of chronic GVHD. There were three of eight patients who survived disease-free after receiving this reduced-intensity regimen.

Together, these reports suggest that while a successful outcome is possible after unrelated donor UCB transplantation for SCD if one adheres to strict criteria for HLA-matching, conditioning regimen intensity and a minimum cell dose, these features alone are not sufficient to ensure a successful outcome in the majority of patients. Thus, it is very likely that improved outcomes will rely upon novel conditioning regimens, alternate donor/recipient HLA matching algorithms, screening for anti-HLA antibodies and perhaps an even higher cell-dose target to overcome the problems of graft rejection and GVHD that currently impede progress.

That the broader application of HCT for SCD is limited is best illustrated by the observation that only 14% of SCD recipients are likely to have a HLA-identical sibling donor [137]. Not surprisingly, lacking a suitable donor is the major barrier to HCT for SCD. An expanded availability of HLA-compatible unrelated donor sources is necessary to pursue HCT as a therapeutic option in most patients with SCD. Donors who are matched at six (HLA-A, -B, and DRB1 loci) to 10 HLA antigens (including HLA-C and DQB1 loci) can be identified via the National Marrow Donor Program in approximately 80% of Caucasian recipients; however, the likelihood of identifying a similarly HLA-matched unrelated donor is less likely in other ethnic groups due to underrepresentation of these groups in the volunteer donor pool and greater HLA diversity. The reduced likelihood of identifying a suitable donor is a difficult problem in HCT for SCD and can limit the application of HCT among those who might benefit most [138–140]. However, the feasibility of identifying suitable donors was suggested by surveys in which 60% of SCD patients had at least one potential suitable unrelated donor, and 26% had three or more potential donors, although in practice, it is still very likely that a suitable unrelated donor will not be identified for most individuals with SCD. For these individuals, utilizing hematopoietic cells from an HLA-mismatched related donor for HCT would be particularly useful. This possibility was suggested by a report of HLA haploidentical bone marrow transplantation in severe SCD that was pioneered by the transplant team at Johns Hopkins University [103]. This approach employed a nonmyeloablative combination of cyclophosphamide, antithymocyte globulin, and fludarabine with 200 cGy TBI before HCT. After the marrow infusion, postgrafting high-dose cyclophosphamide was administered to accomplish in vivo T-cell depletion and to facilitate durable engraftment of donor cells without severe GVHD. In a pilot investigation, 14 recipients of haploidentical HCT were treated and all had prompt recovery after HCT, although six developed graft rejection a median of 151 days after HCT and one patient had low-level donor chimerism with severe anemia after HCT. Nonetheless, 50% of the patients had stable donor engraftment and cessation of sickle-related complications, and none had chronic GVHD. If the complication of graft rejection can be reduced, this would broaden the availability of transplantation to a much larger fraction of patients who otherwise satisfy eligibility requirements but lack a suitable unrelated donor.

Thus, it appears feasible to pursue alternate donors suitably matched at HLA alleles in the treatment of individuals with severe SCD. It is quite possible and even likely that the successful translation of unrelated donor HCT for SCD will hinge on our ability to establish bidirectional donor–host immunologic tolerance, and that this will involve the administration of more intensive immunosuppression than we are accustomed to using in this clinical setting. This represents a shift from the notion that marrow ablation and elimination of sickle cell progenitor cell populations are the principal objectives in carrying out a successful HCT. There are many reasons why this might be, not least of which is that the immunologic *milieu* of SCD is one of inflammation, where innate stimulation of graft-versus-host and host-versus-graft reactions is very likely to occur. In the course of inhibiting these reactions by pharmacologic means, controlling the emergence of opportunistic viral and other infections will take on greater importance than has been appreciated previously after transplantation for hemoglobin disorders.

Conclusion

The track record of HCT from HLA-identical sibling donors for clinically significant hemoglobinopathies is among the best of disorders currently treated by HCT. Most patients with SCD survive after HCT with no evidence of the characteristic clinical sequelae of vaso-occlusion. Moreover, as new indications for HCT emerge and the possibility of alternate donor HCT is expanded, there is likely to be a possibility of HCT for individuals where none existed previously. Nonetheless, very few individuals currently are offered this therapy. Decisions about treatment options in the future are very likely to be influenced by perceptions about the nature of SCD as a chronic illness, and whether the short-term risk of mortality inherent to HCT is balanced by the possibility of survival without symptoms or treatment. While HCT is the only curative therapy for SCD, other treatments such as hydroxyurea and regular RBC transfusion may pose fewer short-term risks and should be considered in selected children who lack suitable donors or in those who exhibit favorable-risk characteristics. Controlled clinical trials comparing chronic transfusions, hydroxyurea, and HCT should be conducted to determine the relative values of these treatments and ultimately provide the optimal care for the SCD patient.

CHAPTER 73

Hematopoietic Cell Transplantation for Immunodeficiency Diseases

Richard J. O'Reilly[1] **and Wilhelm Friedrich**[2]

[1] Department of Pediatrics; Bone Marrow Transplantation Service, Memorial Sloan-Kettering Cancer Center, New York, NY, USA
[2] Department of Pediatrics, University Children's Hospital Ulm, University of Ulm, Ulm, Germany

Introduction

Significant advances in the diagnosis and treatment of severe combined immunodeficiency syndrome (SCID) and other congenital lymphoid immunodeficiencies have occurred since the fourth edition of this book was published in 2008 [1]. Advances in the molecular genetics of these diseases have been particularly noteworthy [2–4]. The genetic causes of over 120 primary immunodeficiency diseases (PID) are now elucidated (reviewed in [5–7]). Identification of these genes and their mutations has radically enhanced precision of diagnosis and led to the discovery of variant mutations as well as modifying genes contributing to phenotypic and functional differences between affected individuals. Newborn screening techniques for detection of SCID and other diseases associated with profound T lymphopenia have now been introduced in several US states, permitting diagnosis in the newborn period and definitive treatment with transplants or gene therapy before the patient develops life-threatening acute or chronic infections. Techniques for transplantation of patients with SCID, WAS, and other lethal genetic immune deficiencies also continue to improve; resulting in survival rates of 80–100% following an HLA-matched related HCT and 50–90% following alternative donor transplants. In this chapter, the results of HCT for SCID, WAS, and other combined lymphoid immunodeficiency syndromes (CID) will be updated, the genetic mutations giving rise to SCID and CID summarized, and the problems still facing physicians caring for these children analyzed.

Immunophenotypic and genotypic variants of severe combined immunodeficiency (SCID)

SCID is a diagnosis that encompasses a heterogeneous group of lethal, genetic disorders each characterized by the absence of antigen-specific T and B lymphocyte responses (reviewed in [1,7,8]). Two overall strata of SCID, based on phenotype are recognized [8]: a typical or "classical" form of SCID marked by T-cell lymphopenia (<300/μL) and responses to phytohemagglutinin (PHA) that are <10% of lower limit of normal, and "leaky" forms distinguished by less severe T-cell lymphopenia (<1000/μL) without maternal T-cell engraftment and a PHA response <30% of lower limit of normal. Based on the number of patients treated for SCID in the United States, the incidence of SCID had previously been estimated to range from 1/50,000 to 1/100,000 live births [5]. However, initial results of large newborn screening programs (see later) indicate that the incidence is approximately 1/58,000 [9]. In contrast to the overall population in the United States, Athabascan-speaking Native Americans, have a high frequency of Artemis gene mutations. As a consequence, a higher incidence of SCID (52/100,000) has been reported in this population [10].

Prior to the identification of the multiple genetic defects that can give rise to SCID, children with classical or typical SCID were classified according to the phenotype and function of their circulating lymphocytes, the mode of inheritance, and/or the presence or absence of adenosine deaminase (ADA), an enzyme deficiency known to be associated with SCID [8,11]. Three major forms of SCID were identified, consisting of the most common form of SCID [B^+ SCID with absent T cells (T^-B^+)], the classical form of SCID (T^-B^-), and ADA-deficient SCID, which may present with either phenotype. Subsequently, mutations in over 15 genes have been shown to give rise to SCID (reviewed in [5–8,12–14]). The currently known genetic defects resulting in SCID affect four major aspects of lymphoid development: (1) metabolic disorders causing premature death of lymphoid precursors due to toxic metabolites (e.g., ADA deficiency) or impaired differentiation (e.g., adenylate kinase 2 deficiency in reticular dysgenesis); (2) defective development resulting from abnormal cytokine signaling (e.g., null mutations of the γc, IL-7Rα, Janus kinase, IL-2Rα, IL-2R/IL-15β genes); (3) defective VD-J gene rearrangement in T-cell and B-cell precursors due to recombinase activating gene defects (RAG1/2) or DNA repair gene defects (e.g., Artemis, DNA ligase IV); and (4) abnormal signaling through the T-cell receptor (CD3/TCR subunit defects, and defects of CD45) (reviewed in [5–8,14]). The genetic disorders causing SCID and their usual lymphoid phenotype are summarized in Table 73.1.

Deficiency of adenosine deaminase, an enzyme involved in purine catabolism, was identified as the first known cause of SCID by Giblett et al. in 1972 [11].In these patients, T cells and, to varying degrees, B cells and NK cells are depleted in the course of their development due to their inability to deaminate deoxyadenosine and adenosine to their metabolites deoxyinosine and inosine. Resultant accumulations of deoxyadenosine and adenosine are toxic to these lymphoid cells and curtail their survival. In reticular dysgenesis, mutations in the mitochondrial enzyme adenylate kinase 2 affect the folding and distribution of proteins essential to T and B cells as well as neutrophil and platelet differentiation [15,16].

Table 73.1 Genetic mutations and phenotypic characteristics of defined variants of severe combined immunodeficiencies

Disease	Circulating T cells	Circulating B cells	Serum Ig	Circulating NK cells	Distinctive features	Inheritance	Genetic defects/presumed pathogenesis
1. T^-B^+ SCID							
(a) γc deficiency	Markedly decreased	Normal or increased	Decreased	Markedly decreased		XL	Null mutations of the GFAC encoding the γ chain of receptors for IL-2, -4, -7, -9, -15, -21
(b) JAK3 deficiency	Markedly decreased	Normal or increased	Decreased	Markedly decreased		AR	Null mutations of the JAK3 signaling kinase gene
(c) IL-7Rα deficiency	Markedly decreased	Normal or increased	Decreased	Normal		AR	Null mutations of the IL-7Rα chain gene
(d) CD45 deficiency	Markedly decreased	Normal	Decreased	Decreased	Normal γ/δ T cells	AR	Null mutations of the CD45 gene
(e) CD3δ/CD3ε /CD3ζ deficiency	Markedly decreased	Normal	Decreased	Normal		AR	Null mutations of genes encoding the CD3δ, CD3ε, or CD3ζ chains of T-cell antigen receptor
2. T^-B^-SCID							
(a) RAG 1/2 deficiency	Markedly decreased	Markedly decreased	Decreased	Normal	Defective VDJ recombination	AR	Null mutations of the recombinase activating gene (RAG) 1 or 2
(b) DCLRE1C (Artemis) deficiency	Markedly decreased	Markedly decreased	Decreased	Normal	Defective VDJ recombination, radiation sensitivity	AR	Null mutations of the gene encoding Artemis DNA recombinase-repair protein
(c) Adenosine deaminase deficiency (ADA)	Absent from birth (null mutations) or progressive decrease	Absent from birth or progressive decrease	Progressive decrease	Normal	Costochondral junction flaring	AR	Null mutations of the ADA gene, elevated lymphotoxic metabolites (dATP, S-adenosyl homocysteine)
(d) Reticular dysgenesis	Markedly decreased	Decreased or normal	Decreased	Decreased	Granulocytopenia, thrombocytopenia (deafness)	AR	Null mutations of the adenylate kinase 2 gene, defective maturation of T, B and myeloid cells (stem cell defect)
(e) DNA ligase IV	Decreased	Decreased	Decreased	Normal	Microcephaly, facial dystrophy, radiation sensitivity	AR	DNA ligase IV defect, impaired non-homologous end joining (NHEJ)
(f) ZAP-70 deficiency	Decreased CD8, normal CD4 cells	Normal	Normal	Decreased		AR	Defects in ZAP-70 signaling kinase
3. Omenn syndrome	Present; restricted heterogeneity	Normal or decreased	Decreased, except increased IgE	Normal	Erythroderma, eosinophilia, adenopathy, hepatosplenomegaly	AR	Hypomorphic mutations allowing residual activity, usually in RAG1 or 2 genes but also in Artemis , IL-7Rα and RMRP genes

Of the $T^-B^+NK^-$ forms of SCID, the X-linked form of ($T^-B^+NK^-$) SCID, accounts for approximately 50% of all cases. This disorder is caused by mutations within the γ chain of the common cytokine receptor, γc [17,18]. The most common autosomal recessive form of $T^-B^+NK^-$ SCID is caused by mutations within the Janus kinase 3 (JAK3) gene [19,20]. Another rare variant of (T^-B^+) SCID with absent circulating NK cells is caused by mutations within the IL-2R/IL-15β subunit [21]. On the other hand, infants with T^-B^+ SCID who have circulating NK cells may have defects within the α chain of the IL-7 receptor [22] or null mutations within the δ, ε, or ζ invariant chains of the CD3 subunit of the CD3/TCR complex [23,24]. Children with $T^{lo}B^+NK^+$ SCID have also been described who have mutations within genes encoding CD45 [25], hypomorphic mutations within the invariant chains of the CD3 receptor (reviewed in [23]) or IL-2Rα [26], and mutations in the CHD7 gene resulting in $T^-B^+NK^+$ SCID with dysmorphic features associated with the DiGeorge and CHARGE syndromes [27].

A T^-B^- SCID phenotype is observed in patients with defects in the recombinases, RAG1 or RAG2 [28–30], mutations of Artemis affecting DNA repair enzymes critical to lymphoid development [31,32] (one of which is particularly prevalent in the Navajo Nation [10]), and the gene encoding ADA (reviewed in [11]). Two other genes affecting DNA repair, DNA ligase IV [13] and Cernunnos-XRCC4-like factor [12] (see cited immunodeficiencies later), usually present as combined immunodeficiencies with detectable T-cell function but progress to a T^-B^- SCID phenotype. ZAP-70 [33–35] and p56lck [36] defects usually result in patients with T cells, but absent CD8 or CD4 cells, respectively. However, genetic analyses of patients diagnosed with SCID have shown that patients with ZAP70 mutations may also present with a full T^-B^- phenotype [35,37]. Abnormal CD7 [38] expression has also been associated with SCID; however, the specific gene mutations involved have not yet been identified.

Several large centers have now analyzed the distribution of SCID genotypes in patients referred for treatment [39–42]. While there is some center-to-center variation, likely reflecting differences in gene frequency among different ethnogeographic groups, X-linked $\gamma c^{-/-}$ SCIDs are the most prevalent (20–46%), followed by the ADA deficient (5–16%), IL-7 $R\alpha^{-/-}$ (5–10%), $JAK3^{-/-}$ (7–13%), RAG1/2 defects including Omenn syndrome (3–23%), and Artemis gene defects (1–12%). Other variants of SCID identified are rare, accounting for no more than 1–5% of any series. In addition, for at least 7% of patients with SCID currently referred, the genetic defects remain to be identified.

Clinical features of SCID

In the absence of a positive family history, children with SCID generally reach medical attention at 3 to 6 months of age coincident with waning protection afforded by passively transferred maternal antibodies. Most children with SCID present with failure to thrive, refractory thrush, persistent diarrhea, recurrent otitis media, and/or interstitial pneumonia secondary to *Pneumocystis jiroveci*, cytomegalovirus (CMV), or common respiratory viruses, such as respiratory syncytial virus (RSV), parainfluenza, adenovirus, or influenza [43–46].

Some genetic causes of SCID exhibit distinctive clinical features, which are also included in Table 73.1. Children with genital and oral ulcers usually have Artemis mutations [10,31,32]. Infants with

Omenn syndrome (scaling erythroderma, lymphadenopathy, organomegaly, eosinophilia, high IgE levels [47]) most frequently have hypomorphic defects within recombinase activating genes (RAG1/RAG2) [28–30] and less commonly within the Artemis [48] or IL7-Rα [49] gene. Microcephaly, developmental delay, and photosensitivity are common in SCID syndromes associated with genes involved in repair of DNA double-strand breaks by non-homologous end joining, such as DNA ligase IV [13,50,51]. Adenosine deaminase deficiency [11,52] can be associated with skeletal, renal, hepatic, and neurologic defects, which may persist despite successful correction of SCID by HCT [53]. Rare children with SCID present with short-limbed dwarfism and ectodermal dysplasia [54]. Patients with reticular dysgenesis, a T^-B^- variant of SCID also present with neutropenia thrombocytopenia and sensorineural deafness [15,55,56]. Cartilage–hair hypoplasia [57,58], which can present as a $T^-B^+NK^-$ SCID, and is caused by mutations in the RNA component of the mitochondrial RNA processing endoribonuclease [59] which maps to chromosome 9P21-P12 [59], also presents with short stature, metaphyseal chondrodysplasia, sparse hair and, in some cases Hirschsprung disease.

In addition, an as yet poorly defined proportion of patients with documented mutations in genes associated with SCID present with levels of T cells and T-cell function that exceed those usually associated with the diagnosis of SCID. Identification of the genes mutated in these “leaky” variants of SCID [8] has also demonstrated the potential of different mutations within the same gene to induce different clinical and immunologic features of disease. Such “leaky” forms of SCID are also extensively documented in murine models bearing mutations in the same genes [60–62]. A striking example of this variation can be observed among patients with null or hypomorphic mutations of RAG1. Null RAG1 [28] mutations can be associated with classical ($T^-B^-NK^+$) SCID, while hypomorphic mutations that preserve some recombinase activity can cause Omenn syndrome as well as a syndrome characterized by oligoclonal T cells, autoimmune cytopenias, and increased risk of CMV infections [28–30,63]. In addition, certain mutations of RAG1 or 2 have been described that result in only mildly diminished recombinase activity. These patients present later in life with normal numbers of T, B, and NK cells but variable degrees of immunoglobulin deficiency and outgrowths of autoaggressive T cells causing an extensive and destructive granulomatous disease [64]. Patients with “leaky” forms of SCID, have also been recognized in several other genetically defined SCID variants, particularly among patients bearing mutations in genes affecting DNA repair including Artemis [48], the DNA protein kinase catalytic subunit (DNA-PKCS), and DNA ligase 4 [12,65]. Such “leaky” features are occasionally observed even in patients bearing mutations in the γc receptor associated with X-linked $T^-B^+NK^-$ SCID and in ADA^- SCID.

Such differences in presentation have also been recorded within single sibships bearing mutations in RAG1/RAG2 [29,30] or Artemis [48]. In addition, significant differences in severity of T- and B-cell cytopenia as well as functional parameters such as responses to mitogens have been reported in siblings with ADA deficiency [33]. These variations within single sibships suggest that other genetic or microenvironmental factors (e.g., thymic stromal function [66] or effects of infection) can modulate expression of mutated and defective gene products, thereby modifying their clinical sequelae.

Unexpectedly high numbers of T cells in a patient with a SCID genotype may also be observed particularly in NK-deficient forms of SCID as a result of the engraftment of transplacentally derived maternal T cells [67–69]. In our own series, over 90% of patients with X-linked, $\gamma c^{-/-}$ SCID have detectable populations of maternal T cells in the blood. While engraftment of maternal $CD4^+$ T cells may cause GVHD, maternal $CD8^+$ T cells rarely cause this complication [68].

Early detection of SCID: the potential impact of prenatal diagnosis and newborn screening on transplant outcome

Historically, recognition of the defects in T- and B-cell function characteristic of SCID permitted early identification of patients with SCID only in siblings of relatives of previously diagnosed patients. Subsequent elucidation of many of the genetic mutations that give rise to SCID has increased the proportion of infants who can be diagnosed in utero [70–73]. For such cases, experienced centers now regularly plan for and provide curative transplants in the newborn period [45,71–74]. The results of such early transplants underscore the advantages of grafting patients with SCID prior to acquisition of infection. In the original study of Myers et al. [75], long-term survival was observed in 21 of 22 infants (95%) transplanted with T-cell-depleted HLA haplotype-disparate parental marrow within the first 28 days of life, compared to 51 of 67 children (76%) who received such transplants at later time points. The significantly improved results for matched and HLA disparate related and unrelated transplants in patients with SCID transplanted ≤3 months of age has subsequently been confirmed by several centers [45,76]. These results also provided a major stimulus for the development of adequately sensitive and specific diagnostic tests that permit screening of large populations of newborns for severe combined immune deficiencies.

Functional T cells, during development in the thymus, undergo V-D-J gene rearrangements to generate an α/β T-cell receptor (TCR). In doing so, these T cells also generate T-cell receptor excision circles (TRECs), which Douek et al. [77] showed could be quantitated and used as a measure of recent thymic emigrants in the blood. Subsequently, Chan and Puck [78] developed an assay permitting measurement of the DNA of one specific TREC, the γRec-ΨJa signal joint TREC, which is produced by at least 70% of developing T cells in the course of generating an α/β TCR. Puck et al. [79] subsequently showed this assay to be useful for screening large populations of newborns, demonstrating that in patients with severe T lymphopenia, including all patients with SCID, TREC levels are low or absent. They also demonstrated that TREC levels could be accurately measured by quantitation of PCR amplified TREC sequences in dried blood samples excised from Guthrie cards used to screen newborns for metabolic diseases. In 2008, Wisconsin initiated a statewide screening of all newborns using this approach [80]. In a report analyzing results of the first 3 years of this program [81], they screened 207,696 infants, of whom 33 patients (incidence 1 : 41,848) were confirmed to have severe T lymphopenia, including five patients with absence of TRECs who were confirmed to have SCID and four patients with DiGeorge syndrome. Other conditions resulting in T lymphopenia included patients with multiple chromosomal abnormalities as well as newborns with complex vascular and lymphatic malformations. The reproducibility, sensitivity, and specificity of the TREC assay for detecting severe lymphopenia were excellent, with false positives largely confined to tests of premature infants of <37 weeks gestation. Recently, in an analysis of over 3 million infants screened in 10 states and in the Navajo Nation, Kwan et al. [9] detected 52 patients with SCID or a leaky variant thereof (incidence 1 : 58,000). Results from this 10-state screening program have identified some geographical differences in the prevalence of specific SCID variants, and also suggest higher incidences among specific ethnogeographic groups, such as the Hispanic population in California [9].

Early estimates of the impact of newborn screening on treatment outcomes are also very encouraging. Although the number of children with SCID, or a leaky variant thereof, who have been identified by newborn screening is limited, the recent report from Kwan et al. [9] indicates that of the 52 patients detected in the 10-state study, 49 were rapidly referred for a transplant, enzyme replacement or gene therapy of whom 87% are surviving at various stages of immune reconstitution.

HCT for SCID

Attempts to correct the lethal immune deficiencies have led to several benchmarks in human HCT, including the first successful allogeneic transplants to employ HLA-compatible marrow from a sibling to correct the immune deficiencies associated with SCID [82] and Wiskott–Aldrich syndrome [83], the successful use of marrow transplants from HLA-compatible unrelated donors [84], and the demonstration that HLA haplotype disparate parental marrow grafts adequately depleted of T cells could reconstitute children with SCID without inducing graft-versus-host disease (GVHD) [85,86]. Initial corrections of a human disease by gene therapy were also achieved in patients with SCID [87]. In this section, we will first discuss results of HLA-matched related transplants, and, thereafter, review results of matched unrelated marrow grafts, HLA haplotype disparate T-cell-depleted grafts and cord blood grafts.

Unmodified HLA-matched related HCT

The first successful human allogeneic HCT was reported in 1968 by Gatti et al. in a patient with X-linked SCID [82], who currently remains alive and well over four decades later. Transplantation of T-cell-replete HCT from an HLA genotypically identical sibling remains the treatment of choice for infants with SCID.

Results of HLA-matched transplants for SCID have significantly improved from the 48% long-term survival reported in 1979 [1,88] to 80–100% in current series [69,89–91]. An update of the long-term results of transplants for SCID in Europe from 1968 to 1999, demonstrated an 81% 3-year survival in 104 recipients of an HLA-matched sibling BMT and over 90% for patients transplanted after 1995 [76,90]. Earlier disease diagnosis, improved supportive care, and particularly, better detection, treatment and prevention of opportunistic infections, have contributed to the improved outcome of SCID transplants from all donor sources. Indeed, in the recent Primary Immune Deficiency Transplant Consortium (PIDTC) analysis of 240 children transplanted for classical forms of SCID between 2000 and 2009, the 5-year survival rates for recipients of HLA-matched related grafts for patients transplanted <3.5 months of age or without active infection were 100% and 100% respectively, compared to 93% for patients with active infection at time of transplant [69] (Figure 73.1a).

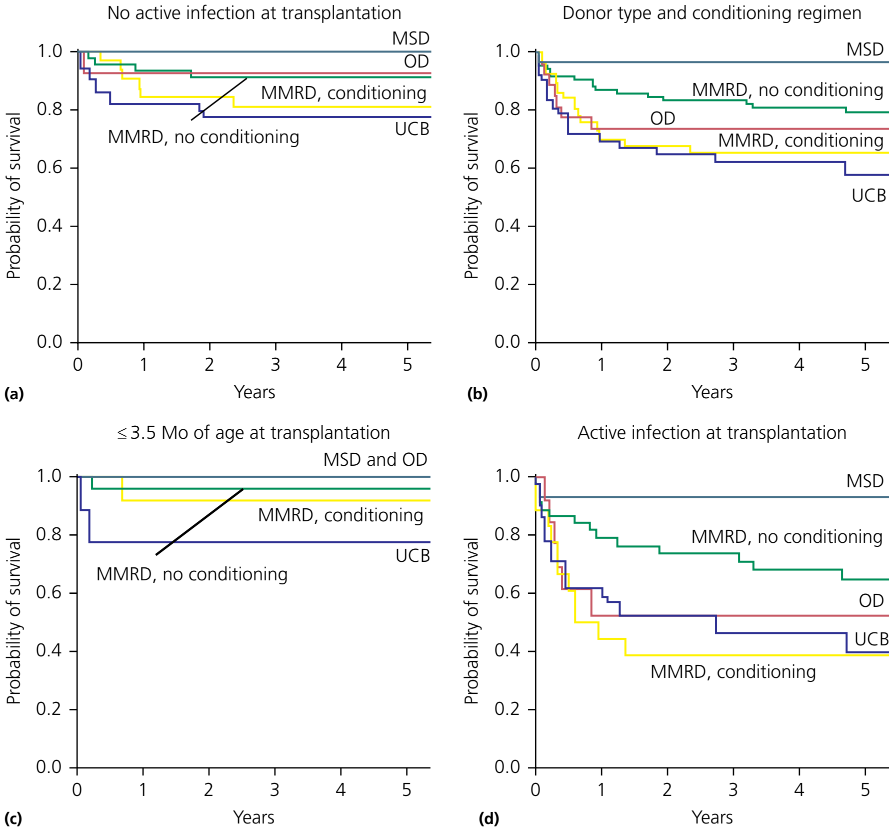

Figure 73.1 Kaplan–Meier estimates of 5-year survival for 240 patients with classical forms of SCID evaluated by the Primary Immune Deficiency Treatment Consortium (PIDTC) who received transplants between 2000–2009. (a) Effect of age at transplant on survival for recipients of matched sibling donor (MSD), other related and unrelated donors (OD), T-cell-depleted mismatched related donors (MMRD) or unrelated cord blood donors (UCB) transplants. (b) Effect of donor type and conditioning on survival in the same groups. (c) and (d) Survival following transplants from different donor types with or without conditioning in (c) – patients without active infection at time of transplant, and (d) – patients with active infection at time of transplant. For most patients with SCID who receive an HLA-matched sibling graft, including those with functional NK cells and "leaky SCID" patients with a marginal in vitro T-cell proliferative response to phytohemagglutinin (PHA), pretransplant cytoreduction is not necessary to ensure engraftment. An important example of this is ADA-deficient SCID. A recent EBMT analysis of 54 patients with ADA-deficient SCID ($T^-B^-NK^+$) who received either a matched sibling (n = 42) or matched related graft (n = 12), almost always without conditioning, recorded 10-year DFS rates of 83% and 81%, respectively [92]. However, in patients with reticular dysgenesis (SCID with severe neutropenia and thrombocytopenia), administration of cytoreduction has been found to be required to achieve consistent engraftment of hematopoietic as well as lymphoid progenitors [90]. Nevertheless, with cytoreduction, DFS rates of 75% or more have been reported [90].

Following HLA-matched HCT for SCID, prophylaxis for GVHD is usually not given due to the low (0–25%) incidence of significant GVHD in these infants [69,89,90]. For example, of 22 consecutive patients who have received an unmodified HLA-matched sibling BMT for SCID administered without pretransplant cytoreduction at MSKCC since 1974, 18 (95%) survive with immune reconstitution; none have developed GVHD despite lack of prophylaxis and infusion of unmanipulated BM containing a median (range) of 7.18×10^8 ($2.5–10.9 \times 10^8$) total nucleated cells/kg. The low incidence of acute and chronic GVHD may in part be due to the absence of any preexisting tissue injury from cytoreduction [93] as well as the young ages of the patients and their matched siblings.

Immune reconstitution following unmodified HLA-matched related marrow transplants

Following infusion of BM from an HLA-matched sibling, homeostatic proliferation of memory T cells infused with the graft results in normal numbers of circulating T cells within 2–4 weeks post-HCT and rapid restoration of mitogen-induced and antigen-specific T-cell responses [46,89,94,95] (Figure 73.2). Circulating naïve CD45RA$^+$ T cells generated from bone marrow-derived lymphoid precursors that have undergone thymic education are usually not detected until 3–4 months post-HCT. Following an unmodified HLA-matched related HCT, specific B-cell function usually develops by 1 year post-transplant, allowing cessation of monthly intravenous gammaglobulin therapy and subsequent re-immunization [46,89,95]. We have analyzed 10 consecutive recipients of an unmodified HLA-matched sibling BMT administered without preparatory cytoreduction, between 1987 and 2005. All made specific antibody production following vaccination with routine childhood immunizations. None remain on intravenous gammaglobulin.

Alternative donor transplants for SCID

HLA-matched unmodified unrelated BMT for SCID

The first successful unrelated HCT for the treatment of SCID was performed in 1973 by O'Reilly and colleagues [84]. The stem cell source was bone marrow derived from a one-HLA class I antigen disparate female donor which was administered to a male infant with T^-B^- SCID. After multiple transplants from this donor, lymphoid engraftment and full immunologic reconstitution was achieved, complicated by the development of extensive chronic GVHD. This patient ultimately died 9 years post-HCT of metastatic squamous cell carcinoma of the skin.

Due to the lack of a bank of HLA typed normal donors, and the success of T-cell-depleted HLA haplotype disparate parental marrow grafts following their introduction in 1981, transplants of unrelated marrow were not significantly explored in the treatment of SCID until the early 1990s. By then, the National Marrow Donor Program had accrued over 1.6 million volunteer donors, and several centers had successfully employed matched unrelated grafts for hematologic malignancies [96].

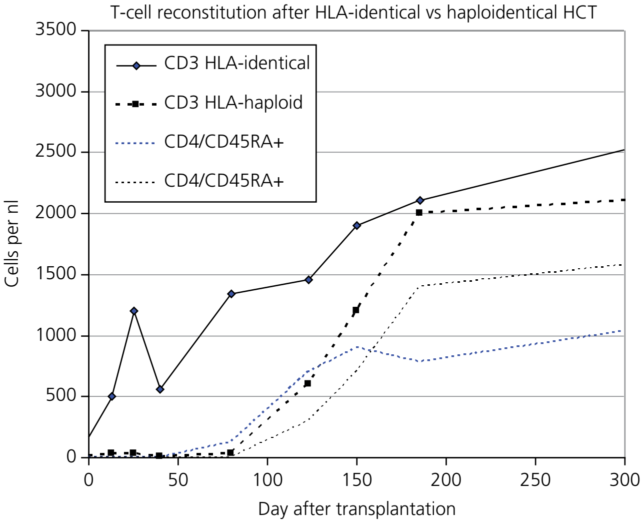

Figure 73.2 Reconstitution of total CD3$^+$ T cells and naïve CD45RA$^+$ CD3$^+$ T cells following unmodified HLA-identical sibling marrow grafts versus T-cell-depleted HLA haplotype disparate parental marrow grafts, each administered without pretransplant conditioning or post-transplant drug prophylaxis for GVHD.

In 1992 Filipovich et al. [97], reported eight SCIDs who received unrelated HCT after cytoreduction with BU/CY, and antithymocyte globulin (ATG), of whom six survived with immunologic reconstitution. An update in 1996 reported 24 SCID patients who received unrelated BMT [98]. The estimated 3-year survival was 61% with grade II–IV GVHD occurring in 17% of engrafted patients [98]. In 2006, Grunebaum et al. [91] reported that, at the University of Brescia and the Hospital for Sick Children in Toronto, 33 of 41 (80.5%) patients who received an unmodified unrelated graft survived with reconstitution of T-cell function; of whom 78% also had B-cell reconstitution. However, acute GVHD was also observed in 73% of patients. Similarly, Newcastle upon Tyne and Great Ormond Street, reported 17 SCID patients who received unmodified matched unrelated grafts after cytoreduction with treosulfan and either fludarabine or cyclophosphamide, of whom 15/17 (88%) survived with T-cell and 9/17 (53%) with B-cell reconstitution [99]. Sequential reports from the European registry Stem Cell Transplant for ImmunoDeficiencies (SCETIDE) documented a 3-year survival rate of 63% for the initial 28 SCID recipients of MUD BMT [90] and 69% for SCIDs who received MUD transplants between 1995 and 2005 [76]. In the PIDTC study, of 240 SCID patients transplanted between 2000 and 2009, 5-year survival for recipients of MUD grafts was 74% [69]. Strikingly, for 186 SCID recipients of T-cell-depleted HLA haplodisparate related grafts transplanted in the same period, 3-year survivals were 66% and 80% for patients who did or did not receive conditioning, respectively [69]. Thus, results of MUD transplants and HLA haplotype disparate related TCD grafts were equivalent and had significantly improved, but were still inferior to the 88% 3-year survival rate for recipients of matched sibling grafts (Figure 73.1b).

T-cell-depleted HLA haplotype disparate related donor transplants

The potential of T-cell-depleted (TCD) transplants was initially suggested by early studies in murine models of allogeneic HCT demonstrating that transplants of hematopoietic cells from fetal liver could reconstitute hematopoiesis in irradiated fully allogeneic recipients without GVHD [100]. In 1973, Keightly et al. [101] extended this approach to man, demonstrating the successful use of fully mismatched fetal liver cells to reconstitute a patient with ADA-deficient SCID without severe GVHD. This case and subsequent reports thus indicated that liver cells obtained from fetuses before initiation of thymic lymphopoiesis (approximately 11 weeks gestation in man) could be transplanted without risk of severe GVHD. However, in a 1983 review of 105 fetal liver transplants [102] only 22 durably engrafted and only 20% of patients survived more than 1 year post-transplant. Nevertheless, in those SCID patients who were engrafted with allogeneic fetal liver-derived hematopoietic cells, the fully allogeneic fetal T cells that developed were able to provide effective resistance against exogenous pathogens but were tolerant of cells of the patient [103].

In the early 1970s, von Boehmer et al. [104] and Reisner et al. [105] demonstrated that H-2 incompatible murine marrow and/or spleen cell transplants depleted of T cells with T-cell specific antibody or a T-cell binding lectin, peanut agglutinin, could also reconstitute lethally irradiated recipients without risk of GVHD. In 1981, our group demonstrated that HLA haplotype disparate parental marrow, depleted of T cells by agglutination with soybean lectin followed by E-rosette depletion was able to reconstitute hematopoiesis in a child with leukemia without GVHD [86]. In 1983, we reported the first successful corrections of SCID by T-cell-depleted HLA haplotype mismatched related BMTs depleted of T cells using the same technique [85]. The three infants described did not receive pretransplant cytoreduction or post-transplant GVHD prophylaxis. All three patients achieved long-term stable donor T-cell chimerism with normal T-cell function and, without acute or chronic GVHD. Similar results with haploidentical SBA$^-$E$^-$ BMT for the treatment of SCID were subsequently reported from the University of Ulm, Germany [43], the University of California Medical Center at San Francisco [106], and Duke University Medical Center, NC [89]. Transplants of TCD HLA disparate related marrow are now the most common type of transplant administered to patients lacking a matched related donor. In the most recent SCETIDE analysis, of 338 patients transplanted for SCID between 1995 and 2005, 25% received genotypically or phenotypically matched related grafts; 20% matched unrelated transplants, and 55% HLA-mismatched TCD transplants from related donors [76]. Similarly, of the 240 patients reported in the PIDTC study, 132 (55%) received HLA disparate T-cell-depleted grafts [69].

The techniques for T-cell depletion that have been utilized for transplantation of infants with SCID include soybean agglutination followed by E-rosette depletion (SBA$^-$E$^-$) [85,86], E-rosetting alone [107], antibody-mediated techniques, such as treatment of the graft with OKT3 [108] or alemtuzumab [109,110], and positive selection of CD34$^+$ progenitors from granulocyte colony-stimulating factor (G-CSF) mobilized PBMC, with or without further T-cell depletion by E-rosetting or monoclonal antibody treatment [69,111]. These techniques differ significantly in their potential to deplete T cells from marrow or cytokine mobilized progenitor cells in the peripheral blood (PBSC). SBA$^-$E$^-$ marrow grafts and CD34$^+$ PBSC selected on the CliniMACS® device reduce T cells by 3 × $\log_{10}$ and 4 $\log_{10}$, respectively [112,113] and have usually been administered without post-transplant GVH prophylaxis. In contrast, T-cell depletion by E-rosetting or treatment with murine T-cell-specific monoclonal antibodies depletes T cells by no more than 2 $\log_{10}$; and the alemtuzumab antibody reduces T-cell numbers by 2.5 $\log_{10}$ [112]. Such transplants have, in the vast majority of cases, only been administered in combination with post-transplant immunosuppressive drugs to prevent GVHD.

Rigorously T-cell-depleted transplants administered without post-transplant immunosuppressive prophylaxis have been associated with low incidences of acute and chronic GVHD and a high probability of survival with full T-cell reconstitution. For example, at our center, SBA$^-$E$^-$ HLA haplotype disparate marrow grafts have been administered to 78 consecutive children with classical or "leaky" forms of SCID since we introduced this approach in 1981, of whom 66% are surviving up to 31 years post-transplant with T-cell reconstitution in all, and B-cell reconstitution in those patients who received myeloablative conditioning (Figure 73.3). The incidence of grade II–IV acute GVHD is 10% at a median follow-up of 18 years. Three patients (6%) died of complications of GVHD. Similarly, Duke University has reported results for HLA haplotype disparate SBA$^-$E$^-$ BMT used to transplant 145 patients with SCID without conditioning pretransplant. Of these patients, 109 (75%) survive with T-cell and, 41% with B-cell reconstitution; 99 (69%) as a direct consequence of the transplant. In this series, the incidence of grade III–IV acute GVHD has also been low (10%). No patient died of GVHD [39,89].

Experience with less rigorously T-cell-depleted HLA haplotype disparate grafts administered with post-transplant administration of drugs such as cyclosporine to prevent GVHD has been associated with a somewhat higher incidence of post-transplant mortality due to GVHD and/or infections. The proportions of patients achieving long-term survival with reconstitution of at least T-cell function have ranged from 56% to 64% in single-center series [46,107,110,114]. In the SCETIDE report of children with SCID transplanted from 1983–1995, the majority of HLA haplotype disparate marrow grafts performed by centers in Europe were depleted of T cells by these less rigorous techniques. The overall survival following such grafts was 52%. The main causes of death were infections (56%), and GVHD (25%) [90].

The introduction of logistically simpler and more effective systems for T-cell depletion based on immunoadsorption to antibody-coated paramagnetic beads has permitted rapid purification of CD34$^+$ progenitor cell fractions from GCSF-mobilized PBSC. Such transplants provide high doses of CD34$^+$ progenitors (5–10 × 10^6/kg) while limiting the T-cell doses to <10^4 CD3$^+$ T-cells/kg. Such grafts can also be administered without post-transplant immunosuppression. At Ulm University, (Figure 73.4) of 71 patients with SCID transplanted with such CD34$^+$ selected, T-cell-depleted grafts fractionated on the CliniMACS device, after busulfan-based conditioning, 70% are surviving with engraftment and reconstitution of T- and B-cell function. Of 11 additional cases who were transplanted without conditioning, 72% survive with T- but not B-cell reconstitution.

In the SCETIDE report of 186 patients with SCID who have received HLA haplotype disparate grafts depleted of T cells by this approach since its introduction in 1996, most of whom also received pretransplant conditioning, 68% were surviving with at least T-cell reconstitution at a median follow-up of 3 years, a result equal to the 68% probability of survival reported by the same group for 66 recipients of marrow grafts from HLA-matched unrelated donors [76].

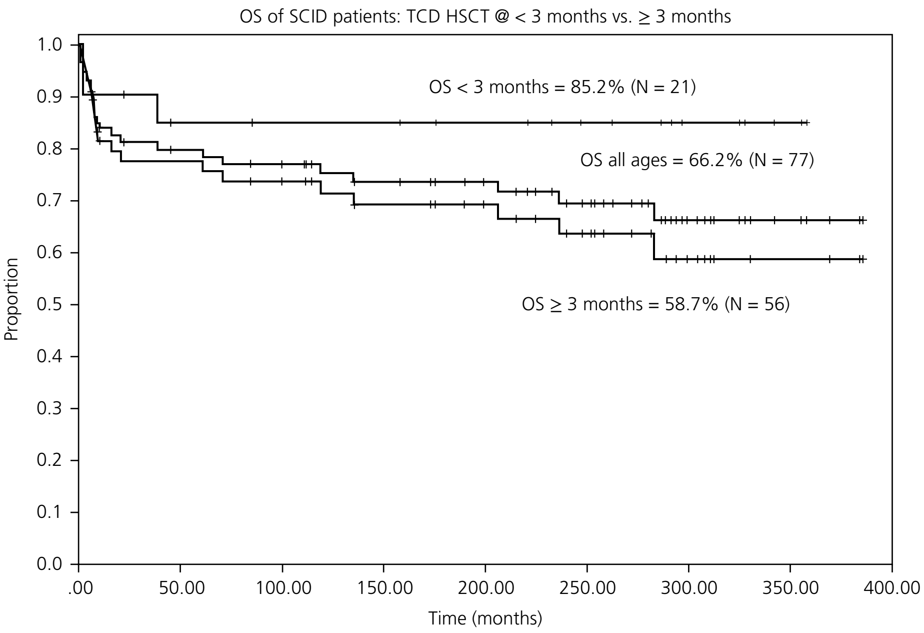

Figure 73.3 Kaplan–Meier estimates of 30-year survival for 71 consecutive patients with classical or "leaky" forms of SCID who received HLA haplotype disparate parental marrow grafts at MSKCC that were depleted of T cells by SBA lectin agglutination and E-rosette depletion. Overall survival (OS) and survivals for patients transplanted before and after 3 months of age are plotted.

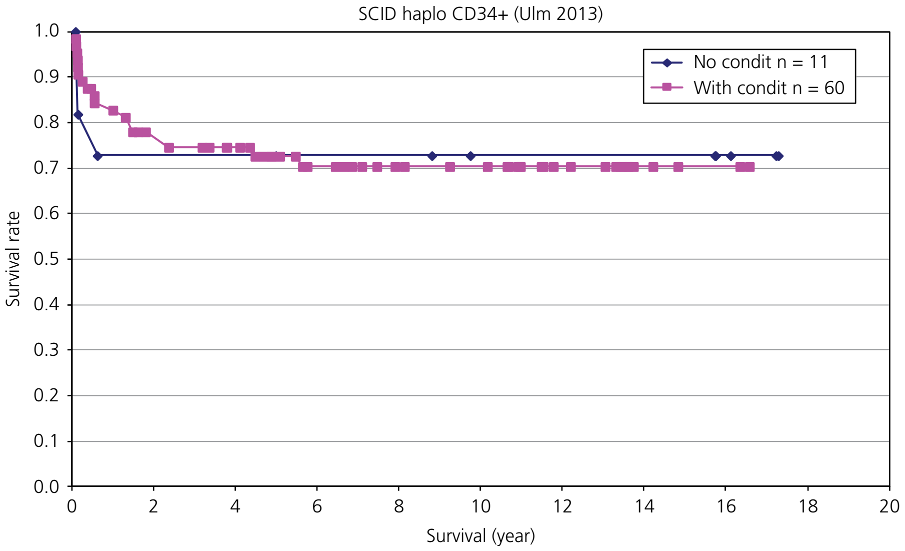

Figure 73.4 Kaplan–Meier estimates of 15-year survival for 71 consecutive patients with classical or "leaky" forms of SCID who received HLA haplotype disparate related transplants at Ulm University that were depleted by positive selection of CD34$^+$ hematopoietic precursors.

In the PIDTC study, of 137 HLA-mismatched grafts, 121 (89%) were depleted of T cells by either the lectin technique or CD34 selection. Overall 5-year survival for this group was 79% for patients who did not receive conditioning and 66% for those who did [69].

Experience with TCD HLA haplotype disparate transplants administered to children with SCID has also led to the recognition of several characteristics of the transplant host that can limit ultimate survival. The most important of these are the age and infection status at the time of transplant. In addition, phenotypic and genotypic characteristics of the patient's variant of SCID may contribute to delayed engraftment or graft failure and impaired reconstitution of lymphoid lineages [90]. Additional modifying influences that have been found to be significant include the type of T-cell depletion employed (e.g., SBA$^-$E$^-$ BMT have resulted in better outcomes than TCD BMT depleted by antibodies in T$^-$B$^-$ SCID [69,90]), the presence or absence of acute GVHD requiring treatment in the patient, and the experience of the transplant center with transplants for SCID [90].

Older patient age and the presence of infection at transplant were first identified as risk factors associated with poor transplant outcomes for patients with SCID by Stephan et al. [46] in 1993 and confirmed by Buckley et al. [89] in 1999 and most recently in a retrospective analyses of patients transplanted for SCID in Europe between 1968 and 2005 [76] and North America between 2000 and

2009 [69]. The striking advantages of a transplant administered to patients with SCID in early infancy was first demonstrated by Myers et al. [75] who reported a 95% survival rate for 22 infants with SCID transplanted within the first 3.5 months of life, 19 of whom received haplodisparate $SBA^{-}E^{-}$ BMT. Only one patient in that series developed an opportunistic infection. Similarly, Brown et al. [45] analyzed 108 patients with SCID, comparing 48 who were the first affected in the family and were not diagnosed until a median of 143 days of age with 60 siblings who were diagnosed either antenatally or at birth. Of those receiving HLA haplotype disparate TCD grafts, 87.5% of the siblings diagnosed at or before birth survived with reconstitution compared to 50% of the transplanted probands. Most of this difference was attributed to reductions in infection-related mortality in the sibling as compared to the proband group.

The relative contributions of earlier transplant and infections have recently been analyzed by the PIDTC. In this series, the age distribution of the 240 patients at transplant was bimodal, with an inflection at 3.5 months. Strikingly, 5-year survival rates for the younger infants who received HLA haplotype disparate T-cell-depleted related grafts, unmodified matched grafts from unrelated donors or cord blood transplants (95%, 100%, and 77%, respectively) did not differ significantly from that of matched sibling grafts (100%). In contrast, survival rates were significantly inferior to that of matched siblings in patients transplanted after 3.5 months of age. However, for those patients transplanted at any age who did not have an active infection or whose prior infection had resolved, 5-year survival rates were 90% and 82%, respectively [69]. These studies underscore the potential impact of early diagnosis and transplant, prior to development of infectious complications, to long-term outcome, particularly when immediately accessible HLA haplotype disparate are the donors.

The PIDTC study also demonstrated that for patients of any age with active infection at the time of transplant, pretransplant conditioning of any type prior to any transplant other than a matched sibling graft was associated with a significantly reduced 5-year survival (matched unrelated 55%; CBT 40%; TCD haplotype disparate transplants 39%) compared to matched sibling grafts and TCD mismatched grafts administered without conditioning (93% and 65%, respectively). Thus, for infants with a classical SCID phenotype [8] with active infection, an initial transplant without conditioning provides a higher likelihood of 5-year survival (Figure 73.1c vs. d).

While these findings bring into question the necessity or even the advisability of conditioning in infected patients presenting a classical SCID phenotype who are to receive transplants other than a matched sibling graft, the relatively large cumulative experience with HLA haplotype disparate TCD grafts in children with SCID has also demonstrated that "leaky" forms of SCID [8] and specific variants of SCID distinguishable by both functional phenotype and genotype, exhibit varying degrees of resistance to initial engraftment of donor hematopoietic cells and reconstitution of T cells and their function. Furthermore, if myelosuppressive conditioning is not employed, engraftment of donor B cells and reconstitution of humoral immunity is uncommon irrespective of the patient's variant of SCID.

The mechanisms contributing to resistance to engraftment of T-cell precursors in HLA disparate T-cell-depleted transplants, and to engraftment and development of B cells irrespective of transplant type in different variants of SCID, are still unclear. However, analysis of patients transplanted for these disorders as well as studies of murine models of these gene defects have provided correlative evidence implicating specific cell systems in the host as mediators of this resistance.

NK cells have been well documented to contribute to graft resistance in murine models of marrow transplantation [115]. Our group and others have also correlated the level and functional activity of host NK cells with graft failure in unconditioned SCID patients [109,116–118]. However, this correlation was not initially observed in the large series transplanted at Duke [89] although in subsequent analyses of their series, they do note that patients with the NK^{+} RAG1 and RAG2 variants of SCID have had markedly delayed reconstitution and have more frequently required secondary "booster" transplants [119]. Whether these discrepancies reflect differences in the function or maturation of NK cells in different genotypic variants of SCID, or interactions of HLA haplotype disparate donor hematopoietic cells with the genetically determined inhibitory and activating killer immunoglobulin-like receptors (KIR) expressed by host NK cells is still unclear. In an analysis of patients with NK^{+} SCID transplanted by the Duke group, donor KIR ligand absence was not significantly correlated with failure to reconstitute T-cell functions, but the group analyzed was small ($n = 22$) [120].

Residual T cells in the host may also contribute to the graft resistance observed in certain variants of SCID. For example, the oligoclonal autoreactive T cells regularly found in patients with Omenn syndrome can react against donor hematopoietic cells [121,122]. Similarly, T cells in ADA-deficient SCID patients including alloreactive T cells can be activated in the presence of ADA provided by normal blood cells [123]. Such T cells likely contribute to the enhanced resistance observed in these patients after TCD BMTs administered without cytoreductive conditioning.

Competition between host and donor thymic precursors for access to niches within the thymus essential to early thymocyte development may also prevent or impair the development and sustained engraftment of marrow progenitors from a normal donor. For example, repopulation of the thymus by wild-type marrow cells is prevented in $RAG^{-/-}$ mice in which the hosts' double negative thymocytes already occupy available sites in the thymic cortex [124]. Hypomorphic RAG1 and DNA ligase 4 mutations may also disrupt the function of epithelial cells in the thymic medulla [66] resulting in markedly reduced generation of Fox $P3^{+}$ regulatory T cells, which may result in the uncontrolled generation of oligoclonal autoaggressive T cells in Omenn syndrome. In contrast, wild-type lymphoid progenitors readily repopulate the thymus and reconstitute T-cell function in $\gamma c^{-/-}$ and $IL\text{-}7R^{-/-}$ mice [66,124]. Results in $IL\text{-}7R^{-/-}$ mice are particularly informative, since $IL\text{-}7R^{-/-}$ variants of SCID are usually NK^{+}.

The presence of transplacentally derived maternal T cells in the circulation prior to transplant could also contribute to graft failures following T-cell-depleted transplants administered without conditioning when haplotype disparate related donors other than the mother are employed. This likely explains the higher rates of engraftment observed in such patients following maternal TCD grafts [125]. Strikingly, maternal T cells can be detected prior to transplant in a proportion of patients with all classical forms of SCID, particularly those with $\gamma c^{-/-}$ variants of SCID who regularly achieve engraftment and reconstitution of donor-derived T cells without conditioning following HLA haplotype disparate maternal TCD marrow grafts, but are rarely detected in patients with Omenn syndrome [46,68,69]. Thus, transplacental engraftment of maternal T cells may provide a surrogate marker of a lack of graft resistance.

The resistance to engraftment that is displayed by certain variants of SCID has had a major impact on the engraftment and function of donor-derived T-cell precursors as well as ultimate outcomes of

HLA haplotype disparate TCD transplants administered without cytoreduction. Thus in our own and the other series 85–100% of patients with γcR$^{-/-}$ and JAK3 mutant T$^-$B$^+$NK$^-$ forms of SCID have achieved engraftment and sustained T-cell reconstitution without cytoreduction [69,89,126]. In contrast, engraftment has been less consistent in patients with the T$^-$B$^-$NK$^+$ variants of SCID if pretransplant conditioning has not been employed [116]. This has resulted in a significantly inferior outcome for these variants. In ADA-deficient SCID, of 40 patients reviewed by Hassan et al. [92], the graft failure rate was 84% for HLA haplodisparate TCD BMT. Even for recipients of unmodified grafts from HLA-matched siblings, the risk was 13%. Similarly, of the 16 ADA$^-$ SCID patients reported by the Duke group [39] who are long-term survivors following a HLA haplotype disparate TCD HSCT without cytoreduction, seven subsequently required an alternate treatment to achieve reconstitution (4 PEG ADA; 2 ADA gene therapy; 1 MUD HSCT with conditioning). Patients with deficiency of CD3δ who present with a T$^-$B$^+$NK$^+$ phenotype also fail to engraft, even after HLA-matched sibling transplants, if they do not receive myeloablative or reduced-intensity myelosuppressive conditioning. In a series of 13 cases, Marcus et al. [127] reported graft failures in 2/2 mismatched related TCD grafts and 1/2 CBT administered without conditioning, while those receiving preparatory conditioning exhibited more consistent engraftment and T-cell reconstitution. Similarly, of six reported patients with IL-7Rα$^{-/-}$ SCID, four failed to engraft after an initial transplant administered without conditioning but engrafted with reconstitution of T-cell immunity after a second transplant administered after conditioning with a busulfan- or fludarabine-containing regimen [44,89,126].

In contrast, engraftment of HLA haplotype disparate TCD marrow or PBSC has been achieved in a high proportion of patients with each of these SCID variants when they have received conditioning with myeloablative or myelosuppressive conditioning regimens including busulfan, thiotepa, or treosulfan together with cyclophosphamide or fludarabine. As a consequence, the probability of reconstitution by donor T cells and sustained normalization of T-cell immunity is markedly improved. For example, in the combined experience of MSKCC and ULM, of 13 patients with ADA$^-$ SCID who received parental SBA$^-$E$^-$ BMT after conditioning with busulfan and cyclophosphamide, all engrafted and 10 (77%) are long-term survivors with T- and B-cell reconstitution [53]. Similarly, Giliani et al. [128] reported 16 patients with IL-7Rα$^-$ SCID. Of the six patients that received cytoreduction prior to a TCD HLA haplotype disparate HCT, all six engrafted with reconstitution of T-cell immunity and long-term survival.

For patients with SCID associated with either Omenn syndrome or reticular dysgenesis, cumulative evidence indicates that at least reduced-intensity conditioning prior to transplant is indicated to secure engraftment and functional reconstitution following a TCD HLA haploidentical related HCT [109]. In patients with Omenn syndrome, early transplants administered without cytoreduction have been associated with a high incidence of graft failure [109,129]. In contrast, Mazzolari et al. [130] reported that 4/5 patients transplanted with HLA haplotype disparate TCD HCT and 3/4 recipients of unmodified marrow from matched unrelated donors transplanted after cytoreduction with busulfan and cyclophosphamide ultimately achieved full engraftment and survived with T- and B-cell reconstitution. Thus, such cytoreduction can overcome the graft resistance thought to be mediated by the small numbers of autoreactive T cells and NK cells consistently detected in these patients. Similarly, in a European compendium of patients with reticular dysgenesis, of five transplanted without high doses of busulfan and cyclophosphamide, none survived with sustained engraftment, while each of five patients treated with this high-dose combination engrafted, of whom three are long-term survivors [131].

Immune reconstitution following HLA haplotype-disparate T-cell-depleted transplants

Following an SBA$^-$E$^-$ T-cell-depleted mismatched related BMT, the majority of patients will develop normal numbers of CD3 (Figure 73.2), CD8, and CD4 T cells by 3–6 months post-HCT, irrespective of whether cytoreduction is employed [1,89]. Approximately 50% of patients will have a normal PHA response by 6 months post-transplant and 80% will have normal T-cell responses to mitogens and antigens by 6–12 months (reviewed in [1,89,90]). Myers et al. [75] also demonstrated that infants who receive an SBA$^-$E$^-$ mismatched parental BMT within 28 days of life develop higher numbers of CD45RA$^+$ and T-cell receptor excision circle (TREC) positive T cells, and more robust T-cell proliferative responses within the first 3 years post-transplant than infants transplanted at later time points. In a large European study of mismatched TCD HCT recipients using a variety of TCD techniques, the median time to develop normal T-cell proliferative responses to tetanus toxoid was 8.7 months [132]. Of the 116 patients in this study who survived at least 6 months post-HCT only 43% of those with absent T-cell function at 6 months ($n = 21$) ultimately developed normal T-cell responses, compared to 71% of those patients with normal or near-normal T-cell function 6 months post-transplant [132]. The quality and kinetics of T-cell reconstitution in the European series correlated with SCID phenotype, with a higher percentage of patients with B$^+$ SCIDs exhibiting normal T-cell function at all time points >6 months post-HCT [132] compared to patients with B$^-$ SCID. Similar findings have been reported in the PIDTC study [69].

Recent evaluations of patients with SCID 10–15 years after successful HLA haplotype disparate TCD grafts have focused attention on those characteristics of host and HCT that sustain thymic output and normal T-cell function. Initially, Patel et al. [133] showed that the average number of TREC$^+$ early thymic emigrant T cells, naïve T cells, and T-cell mitogen responses decreased with time after such transplants suggesting that the pool of thymic precursors transferred in the graft might be limited, leading to accelerated age-associated reduction in thymic output.

Borghans et al. [134] evaluated predictors of long-term T-cell reconstitution in a heterogeneous group of 19 SCID patients evaluated 5–32 years post-HCT. Unlike the patients in the study of Patel et al. [133] who received SBA$^-$E$^-$ HCT without prior conditioning, 74% of patients in this study were cytoreduced and 14 of 19 patients received transplants T-cell depleted by E-rosetting together with post-transplant GVHD prophylaxis. In 11 of 19 patients, there was no evidence of impaired T-cell reconstitution, naïve T-cell production, or reduced telomere length post-HCT when compared to age-matched controls. In the eight patients with impaired T-cell reconstitution late after transplant, these parameters were already abnormal early after HCT, suggesting that impaired engraftment rather than reduced thymic output with time was the etiology of the poor T-cell reconstitution.

In contrast to the findings of Patel et al. [133] and in accord with the findings of Borghans et al. [134], three more recent studies have shown that those patients with SCID who have received haplotype disparate TCD HCT after myeloablative conditioning and who have donor cells in their peripheral myeloid lineages or among the CD34$^+$ progenitor cells in the marrow late after transplant, also have sustained normal levels of TREC$^+$ T cells without evidence of a decline in T-cell numbers or function [114,135,136]. The study of Friedrich et al. [136] is particularly informative, since 25 of the 31 patients studied had received HLA haplotype disparate SBA$^-$E$^-$ T-cell-depleted marrow grafts, either with (n = 13) or without (n = 12) pretransplant cytoreduction. Sustained engraftment of donor type CD34$^+$ progenitor cells was regularly observed in the cytoreduced group and was directly correlated with persistently normal numbers of TREC$^+$ and CD45RA$^+$ T cells. Donor CD34$^+$ cells were not detected in the non-cytoreduced group. In contrast to those transplanted after cytoreduction, patients who had not received pretransplant cytoreduction also exhibited significant reduction of CD45RA$^+$ T cells 15 years post-transplant. Each of these studies supports the ability of the epithelium of the SCID thymus to support robust thymopoiesis in most patients [133–137], for at least two decades. Further follow-up by the Duke group suggests that after the first 10 years, TREC production and T-cell diversity stabilize [138]. However, declines in the generation of naïve thymic emigrant T cells in patients who received no cytoreduction prior to transplant remains a concern [133], and suggests that thymopoiesis may not be sustained if long-term engraftment of hematopoietic stem cells capable of continuously providing thymic precursors is not achieved [135,136]. The use of booster grafts of TCD bone marrow, without cytoreduction, to enhance T-cell function in patients with prolonged poor T-cell reconstitution has yielded mixed results. Slatter and colleagues have reported that boosts of TCD HCT following initial transplant, in the absence of cytoreduction, do not improve T-cell function [139]. However, boosts administered after reduced-intensity conditioning may provide benefit [140].

Reconstitution of specific antibody formation following an SBA$^-$E$^-$ mismatched related HCT, as with other TCD techniques, is usually observed only in those patients given pretransplant cytoreduction that includes alkylating agents that are toxic for hematopoietic stem cells, such as busulfan, treosulfan, thiotepa, or melphalan and is correlated with the degree of donor B-cell engraftment (reviewed in [1,69,99,139]). In the MSKCC series, normal antibody responses following immunization have been observed in all patients engrafted with donor B cells, compared to less than 10% of patients with exclusively host B cells (reviewed in [1]). In a retrospective analysis of 90 patients transplanted at Hôpital Necker-Enfants Malades, Neven et al. [41] also noted that following myeloablative doses of busulfan and cyclophosphamide, transplants of HLA disparate TCD marrow induced both mixed myeloid and B-cell chimerism in a high proportion of cases, with reconstitution of both B- and T-cell immunity. Similarly, Mazzolari et al. [114], who analyzed 40 patients with SCID who received matched related or unrelated unmodified or HLA disparate related TCD grafts, found that only 1/11 patients who received either no conditioning or conditioning with ATG alone engrafted with donor B cells compared to 26/29 patients who had been conditioned with ablative doses of busulfan and/or thiotepa or melphalan. However, in a single-center study by Haddad et al. [141] from the Hôpital Necker-Enfants Maladies, donor B-cell engraftment was documented in only 1/9 recipients of TCD mismatched related BMT administered after cytoreduction with lower dose busulfan (8 mg/kg) and 200 mg/kg cyclophosphamide, compared with 2/8 who did not receive conditioning. Thus, myeloablative doses of busulfan, melphalan, thiotepa, or treosulfan have been required to induce more consistent engraftment of donor B cells and reconstitution of humoral immunity in most recipients of partially matched unrelated and HLA haplodisparate TCD grafts.

The requirement for engraftment of donor B cells and/or their precursors to achieve reconstitution of humoral immunity is far from absolute, however. The argument that endogenous B cells detected in several variants of SCID are intrinsically defective and need to be replaced is not supported by the fact that antibody production is usually reconstituted following HLA-matched grafts without conditioning, even though the B cells are often of host type. This has recently also been demonstrated for a significant proportion of patients transplanted with HLA haplodisparate TCD marrow without conditioning to correct IL-7R$\alpha^{-/-}$, CD3$^{-/-}$, or ADA$^-$ variants of SCID [42,142]. Furthermore, Haddad et al. [141] have shown, by allele typing, that the antibodies detected in such cases are, indeed, of host type. In contrast, reconstitution of antibody production by host B cells is rare in $\gamma c^{-/-}$ or JAK3$^{-/-}$ SCID [42], and not seen in T$^-$B$^-$ forms of SCID associated with mutations affecting V-D-J recombination such as mutations in RAG1, RAG2, Artemis, and DNA ligase IV. Nevertheless, these instances of host B-cell-mediated reconstitution of humoral immunity have spawned an ongoing debate regarding the need, or even the advisability of myeloablative conditioning in many cases. This is a particular concern for infected patients but is also a concern for those diagnosed and transplanted in the newborn period, when myeloablation may, on the one hand, be less effective in securing donor B-cell precursor engraftment because of the resilience of host hematopoietic cells at this age and, on the other, be most likely to induce long-term damage to other developing tissues and organs, including the CNS.

Major challenges for the future thus include: (1) development of better techniques with which to define those patients whose B cells by virtue of their genetic and functional characteristics or their stage of development, can effectively cooperate with donor-derived T cells; (2) exploration of alternative transplant strategies, such as tandem transplants in which an initial transplant is given in the newborn period without cytoreduction to initially reconstitute T-cell function, and a secondary transplant is administered after myelosuppressive treatment at 18–24 months of age when brain development is complete and the patient is otherwise healthy; and (3) the development of less toxic, more targeted approaches to create a niche and/or secure engraftment of donor-derived hematopoietic stem cells and/or B-cell precursors capable of providing long-term reconstitution of humoral immunity.

Many variants of SCID are also associated with deficiencies of NK cells and their functions. Prominent among those are the $\gamma c^{-/-}$ or JAK3$^{-/-}$ variants of SCID. Without pretransplant conditioning, such patients transplanted with HLA disparate TCD grafts or unmodified grafts from matched unrelated donors usually remain NK deficient. Although conditioning with busulfan-containing regimens prior to transplant secures reconstitution of donor-derived NK cells and their function in most patients, it is not achieved in 13–30% of patients with $\gamma c^{-/-}$ or JAK3$^{-/-}$ SCID [41,114,141]. The significance of persistent NK cell deficiencies is not clear. The possibility that continuing deficiency of NK cells observed in patients with JAK3$^{-/-}$ or $\gamma c^{-/-}$ SCID patients post-transplant could contribute to the high incidence of severe HPV-associated warts, has been considered, but this complication has also been observed in patients with those variants of SCID who do achieve reconstitution of NK-cell function [41].

Umbilical cord blood cell (CBC) transplants for SCID

Umbilical cord blood transplants (CBT) have only recently been explored as an alternative source of allogeneic hematopoietic cells for transplantation of children with SCID and other immune deficiencies. However, experience with CBT in leukemia and marrow failure syndromes has demonstrated their potential to provide long-term hematopoietic and lymphoid reconstitution and has also underscored several potential advantages over unmodified unrelated marrow or PBSC transplants from adults, including a significantly reduced potential to induce severe GVHD in recipients of comparable HLA disparity, their immediate accessibility, and the broader applicability of CBTs from current, selectively recruited cord blood banks to patients from minorities underrepresented in international marrow donor registries.

In 2000, Knutsen and Wall [143] described eight infants with severe T-cell immunodeficiency disease who received an unrelated CBC transplant, seven of whom engrafted. Despite significant HLA disparity between cord blood donor and recipient, only one patient developed severe GVHD. T- and B-cell immunity recovered 60–100-days post-transplant. Similarly, Buckley et al. [89] used unrelated CBTs with BU/CY conditioning to rescue two children with X-linked SCID who rejected a TCD mismatched related BMT administered without cytoreduction. More recently, a retrospective analysis conducted by two European registries, Eurocord and Stem Cell Transplant for Immunodeficiencies in Europe (SCETIDE) compared results of CBT and HLA-mismatched related donor-derived T-cell-depleted transplants performed between 1995 and 2005 [144]. In the CBT group ($n = 74$), 67% of the CBT were matched or 1 HLA allele disparate. In contrast, 68% of the MMRD grafts were mismatched for a full haplotype. Although the proportion of patients in the MMRD group who received no or reduced-intensity conditioning was significantly higher, the proportions of patients achieving engraftment were not significantly different (CBT: 86% vs. 78% MMRD). However, the proportion of patients with both myeloid chimerism and independence of IVIG supplementation, was higher in the CBT group, consistent with the higher intensity of conditioning administered to all but 10% of the CBT recipients. Despite the greater level of HLA disparity in the MMRD group, the incidence of grade II–IV acute GVHD was significantly lower (22% in the MMRD group vs. 34% in the CBT group). The overall 5-year survival rate for the CBT group was 57% versus 62% for the MMRD group (NS). However, these good results principally reflect survival of recipients of HLA-matched or 5/6 HLA allele-matched grafts (76% and 62%, respectively). For recipients of CBT that were mismatched for ≥2 HLA alleles, 5-year survival was only 35%. In the recent PIDTC study [69], 43 patients received CBT from HLA-matched or ≥4/6 allele-matched donors. Overall 5-year survival was 58%; 77% for patients transplanted without active infection and 40% for patients with infection at time of transplant (Figure 73.1c, d).

In utero HCT for SCID

In 1996, Flake et al. reported the first successful correction of SCID by a T-cell-depleted haploidentical parental marrow graft administered in utero [145]. This patient had X-linked SCID that was diagnosed during the first trimester. The patient received three infusions of TCD BM cells containing 114.0, 8.9, and 6.2×10^6/kg $CD34^+$ cells and $<5.2\ 10^5$ $CD3^+$ cells/kg fetal weight. The cells were injected into the abdomen of the fetus between 15.0 and 18.5 weeks gestation. Circulating donor T cells were observed at birth, at 3 and 6 months thereafter. However, B cells, NK cells, monocytes, and granulocytes remained of host origin. The engrafted paternal T cells were tolerant to the patient and demonstrated normal in vitro T-cell proliferative responses. Subsequent analysis of this patient has demonstrated persistent engraftment of donor T cells with specific T-cell function and antibody production 4 years post-HCT.

In 2005, Muench et al. [146] summarized the published results of in utero transplants in 10 patients performed between 1996 and 2005, to correct γc- ($n = 5$) or IL-7Rα-deficient SCID ($n = 1$), Omenn syndrome ($n = 1$), or genetically uncharacterized T^-B^+ ($n = 1$), T^-B^- ($n = 1$), $T^-B^+NK^+$ ($n = 1$) SCIDs. Of the 10 patients with SCID, 9 received parental, TCD BM, or PBSC. Engraftment of T lymphocytes with or without donor NK cells was observed in eight patients, of whom seven achieved full functional reconstitution with donor T cells and, where evaluated, NK cells. As shown by Piroveno et al. [147], who had transplanted 5 of these 10 cases, T-cell engraftment and functional reconstitution was consistently observed in patients with the T^-B^+, $\gamma c^{-/-}$, and IL-$7R\alpha^{-/-}$ variants, but was either not detected or remained at low levels in two patients with T^-B^- SCID, of whom one had a RAG2-deficient Omenn syndrome. Furthermore, B-cell reconstitution has been detected in only two patients [145]. Nevertheless, no patients with T-cell engraftment had evidence of GVHD at birth, nor did they develop GVHD thereafter. Furthermore, engrafted and functional paternal graft-derived T cells have exhibited no alloreactivity against host-derived tissues or hematopoietic cells. Thus, although experience with intrauterine transplants for SCID remains very limited, these transplants reiterate both the potential and the limitations of HLA disparate T-cell-depleted transplants administered postnatally. They also indicate that the constraints to engraftment and, particularly, B-cell reconstitution reflect limitations to the development of normal donor-derived lymphoid progenitor cells that are already operative by 20–24 weeks gestation when the transplants have usually been administered.

Long-term complications in patients transplanted for SCID

Experience with transplants for SCID includes many patients followed for over 40 years, and has thus permitted copious assessments of long-term efficacy, the durability, and function of the transplants, and the late complications attributable to these diseases and/or their treatment. As reflected by the 85–100% rates of survival recorded for these patients at intervals of 10, 20, and 30 years post-transplant [39,41,114], recipients of HLA-matched related transplants are, with rare exceptions, in good health and leading normal lives, with stable engraftment of at least donor T cells, and, in most cases, stable reconstitution of both T- and B-cell immunity. Recurrent or severe infections or autoimmune disorders are rare in these patients after the first year post-transplant, by which time immune reconstitution has been achieved [39,41,114]. However, up to 10% of these patients have been reported in one series to exhibit subnormal height and/or weight [114]. This has usually been ascribed to prolonged steroid treatment for GVHD.

Among recipients of HLA-matched unmodified unrelated grafts or T-cell-depleted HLA disparate related transplants, late complications have been more frequent. These have included autoimmune disorders such as hemolytic anemias, autoimmune myositis, thyroiditis, and hepatitis in 2 to 15% of cases [39,41,114], recurrent or chronic sinopulmonary infections in up to 20% of patients [39], and recurrent intermittent gastrointestinal disorders, including diarrhea and GERD not related to GVHD in 16–20% of cases. Each of these complications has occurred more commonly in patients who were transplanted at ≥3.5 months of age [39], and particularly those who still had subnormal numbers and function of T cells at 1-year post-transplant especially those transplanted for T^-B^- variants of SCID, such as the $RAG1^{-/-}$ and Artemis variants [41]. It is also noteworthy that recurrent or protracted sinopulmonary infections are particularly observed among patients requiring supplemental IVIG. Moderate to severe HPV infections involving hands and feet have also been recorded in up to 26% of patients, particularly among patients transplanted for the $\gamma c^{-/-}$ and JAK-3$^{-/-}$ variants of SCID [39,41,114] and have occurred in these patients irrespective of the type of transplant administered.

Certain late complications may also be induced by preparatory myeloablative conditioning, including short stature, sterility, and abnormally formed permanent teeth. However, reliable estimates of these complications are not yet available. Other late abnormalities may be sequelae of the variants of SCID treated, such as the impaired neurocognitive development observed in a proportion of patients transplanted for ADA$^-$ SCID [53], or the result of severe infections, including encephalitis, occurring prior to or in the immediate post-transplant period [41,114].

Transplantation for other combined immunodeficiency syndromes (CID) and life-threatening genetic disorders of lymphocyte development or function

In addition to the hypomorphic or “leaky” genetic variants of SCID, a series of combined immune deficiencies (CIDs) have been identified and recently genetically characterized that affect, to varying degrees, T- and B-cell populations and their functions. These disorders include syndromes associated with profound deficiencies in response to either a broad or narrow range of exogenous pathogens. However, patients with these disorders usually retain a capacity to mount T-cell responses against allogeneic cells. As a consequence, immunoablative and myelosuppressive conditioning is usually required to consistently secure engraftment.

A consensus list of recognized CIDs has recently been reported [148] and those for which transplants have been repeatedly administered are summarized in Table 73.2, along with the distinguishing immunologic and clinical features of each disorder. These CIDs can be roughly divided into seven categories: (1) disorders of nucleotide metabolism, (2) defects of DNA recombination and repair, (3) defects in intracellular signaling molecules, (4) defects in cytokine generation, (5) defects of cytolytic effector function, (6) defects of cytoskeleton plasticity or lymphocyte effector function, and (7) defects of immune regulation.

Each of these disorders can be and has been corrected by an allogeneic HCT from a normal donor. Early results for transplants applied to patients with these disorders were, in aggregate, inferior to those reported for transplants applied to patients with SCID or Wiskott–Aldrich syndrome. For example, in the European experience of HCT for non-SCID patients with T-cell immunodeficiency performed between 1968 and 1993, 3-year overall survival was 63% for 47 recipients of an HLA-matched sibling graft and only 35% in 72 recipients of an HLA-mismatched T-cell-depleted graft [90]. In comparison, survival rates for patients with SCID receiving grafts at the same centers were 81% and 54%, respectively. However, many of these disorders are so rare that experience with allogeneic HCTs as treatment was limited to 1–3 patients at any given center. Recently, however, analyses of the cumulative experiences at collaborating centers specializing in the transplantation of patients with several of these diseases have been reported, permitting better estimates of transplant efficacy in their treatment. The results of such analyses for specific disorders can be briefly summarized.

Table 73.2 Combined immune deficiencies repeatedly corrected by transplantation

Disease	Circulating T cells	Circulating B cells	Serum Ig	Associated features	Inheritance	Genetic defects/presumed pathogenesis
METABOLIC DISORDERS						
(a) Purine nucleoside phosphorylase deficiency (PNP)	Progressive decrease	Normal	Normal or decreased	Autoimmune hemolytic anemia; neurologic impairment	AR	Absent PNP, T-cell and neurologic defects from elevated toxic metabolites (e.g., dGTP)
DISORDERS ASSOCIATED WITH DEFECTS OF DNA REPAIR						
(a) Cernunnos/ XLF deficiency	Decreased	Decreased	Decreased	Microcephaly; in utero growth retardation; radiation sensitivity	AR	Cernunnos defect resulting in impaired NHEJ
(b) DNA ligase IV	Decreased	Decreased	Decreased	Microcephaly; facial dystrophy; radiation sensitivity	AR	DNA ligase IV defect resulting in impaired non-homologous end joining (NHEJ)
(c) Nijmegen breakage syndrome	Progressive decrease	Normal	Often decreased IgA, IgE, and IgG subclasses; increased IgM monomers; antibodies variably decreased	Microcephaly; bird-like face; lymphomas; ionizing radiation sensitivity; chromosomal instability	AR	Hypomorphic mutation in NBS1 (Nibrin); disorder of cell cycle checkpoint and of DNA double- strand break repair
DISORDERS OF INTRACELLULAR AND INTERCELLULAR SIGNALING						
(a) Cartilage–hair hypoplasia	Decreased or normal	Normal	Normal or reduced. Antibodies variably decreased	Short-limbed dwarfism with metaphyseal dysostosis; sparse hair; anemia; neutropenia; susceptibility to lymphoma and other cancers; impaired spermatogenesis; neuronal dysplasia of the intestine	AR	Mutation in *RMRP* encoding the RNA segment of the mitochondrial RNA processing endoribonuclease which, with TERT, modulates cell proliferation
(b) Anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID)	Impaired generation of memory T-cells	Present	Impaired antibody responses	Anhidrotic ectodermal dysplasia + specific antibody deficiency (lack of Ab response to polysaccharides); various infections (mycobacteria and pyogens)	XL	Mutations of *NEMO (IKBKG)*, resulting in impaired NF-κB activation
(c) Anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID)				Anhidrotic ectodermal dysplasia + T-cell defect + various infections	AD	Gain-of-function mutation of *IKBA,* resulting in impaired activation of NF-κB

(*Continued*)

Table 73.2 (*Continued*)

Disease	Circulating T cells	Circulating B cells	Serum Ig	Associated features	Inheritance	Genetic defects/presumed pathogenesis
(d) Dock 8 deficiency-associated autosomal recessive hyper IgE syndrome	Normal	Normal	Elevated IgE	Susceptibility to bacterial, viral and fungal infections; eczema; vasculitis; CNS hemorrhage. No skeletal or connective tissue abnormalities	AR	Dock8 mutations
(e) CD40 ligand deficiency	Normal	IgM and IgD B memory cells present, but others absent	IgM increased or normal, other isotypes decreased	Neutropenia; thrombocytopenia; hemolytic anemia; biliary tract and liver disease; opportunistic infections	XL	Defects in CD40 ligand (CD40L); defective B and dendritic cell signaling
(f) MHC class I deficiency	Decreased CD8, normal CD4	Normal	Normal	Vasculitis	AR	Mutations in *TAP1*, *TAP2* or *TAPBP* (tapasin) genes giving MHC class I deficiency
(g) MHC class II deficiency	Normal number, decreased CD4 cells	Normal	Normal or decreased		AR	Mutation in transcription factors for MHC class II proteins (*C2TA*, *RFX5*, *RFXAP*, *RFXANK* genes)
DISORDERS OF CYTOLYTIC EFFECTOR FUNCTION						
(a) Familial hemophagocytic lymphohistiocytosis (FHL) syndromes						
(i) Perforin deficiency	Normal	Normal	Normal	Severe inflammation; fever; decreased NK and CTL activities	AR	Defects in *PRF1*; perforin, a major cytolytic protein
(ii) Munc 13-D deficiency	Normal	Normal	Normal	Severe inflammation; fever; decreased NK and CTL activities	AR	Defects in *MUNC13D* required to prime vesicles for fusion
(iii) Syntaxin 11 deficiency	Normal	Normal	Normal	Severe inflammation; fever; decreased NK and CTL activities	AR	Defects in *STX11*, involved in vesicle trafficking and fusion
(b) Immunodeficiency with hypopigmentation						
(i) Chediak-Higashi syndrome	Normal	Normal	Normal	Partial albinism; giant lysosomes; low NK and CTL activities; heightened acute-phase reaction; encephalopathic accelerated phase	AR	Defects in *LYST*, impaired lysosomal trafficking
(ii) Griscelli syndrome, type 2	Normal	Normal	Normal	Partial albinism; low NK and CTL activities; heightened acute phase reaction; encephalopathy in some patients	AR	Defects in *RAB27A* encoding a GTPase in secretory vesicles
(iii) Hermansky–Pudlak syndrome, type 2	Normal	Normal	Normal	Partial albinism; neutropenia; low NK and CTL activity; increased bleeding	AR	Mutations of AP3B1 gene, encoding for the β subunit of the AP-3 complex
(c) X-linked lymphoproliferative syndrome (XLP)						
(i) XLP1	Normal	Normal or reduced	Normal or low immunoglobulins	Clinical and immunologic abnormalities triggered by EBV infection, including hepatitis, aplastic anemia, lymphoma	XL	Defects in *SH2D1A* encoding an adaptor protein regulating intracellular signals
(ii) XLP2	Normal	Normal or reduced	Normal or low immunoglobulins	Clinical and immunologic abnormalities triggered by EBV infection, including splenomegaly, hepatitis, hemophagocytic syndrome, lymphoma	XL	Defects in *XIAP* encoding an inhibitor of apoptosis
DISORDERS OF CYTOSKELETON PLASTICITY OR LYMPHOCYTE EFFECTOR FUNCTION						
(a) Wiskott–Aldrich syndrome (WAS)	Progressive decrease	Normal	Decreased IgM: antibody to polysaccharides particularly decreased; often increased IgA and IgE	Thrombocytopenia with small platelets; eczema; lymphomas; autoimmune disease; IgA nephropathy; bacterial and viral infections. XL thrombocytopenia is a mild form of WAS, and XL neutropenia is caused by missense mutations in the GTPase binding domain of *WASP*	XL	Mutations in *WASP*; cytoskeletal defect affecting hematopoietic stem cell derivatives
DISORDERS OF IMMUNE REGULATION						
(a) Autoimmune lymphoproliferative syndrome (ALPS)						
(i) CD95 (Fas) defects, ALPS type 1a	Increased double-negative (CD4− CD8−) T cells	Normal	Normal or increased	Splenomegaly; adenopathy; autoimmune blood cytopenias; defective lymphocyte apoptosis increased lymphoma risk	AD (rare severe AR cases)	Defects in *TNFRSF6*, cell surface apoptosis receptor; in addition to germline mutations, somatic mutations cause similar phenotype, ALPS 1a (somatic)

Table 73.2 (*Continued*)

Disease	Circulating T cells	Circulating B cells	Serum Ig	Associated features	Inheritance	Genetic defects/presumed pathogenesis
(ii) CD95L (Fas ligand) defects, ALPS type 1b	Increased double-negative (CD4– CD8–) T cells	Normal	Normal	Splenomegaly; adenopathy; autoimmune blood cytopenias; defective lymphocyte apoptosis; lupus	AD AR	Defects in *TNFSF6*, ligand for CD95 apoptosis receptor
(iii) Caspase-10 defects, ALPS type 2a	Increased CD4– CD8– T cells	Normal	Normal	Adenopathy; splenomegaly; autoimmune disease; defective lymphocyte apoptosis	AD	Defects in *CASP10*, intracellular apoptosis pathway
(iv) Caspase-8 defects, ALPS type 2b	Slightly increased CD4– CD8– T cells	Normal	Normal or decreased	Adenopathy; splenomegaly; recurrent bacterial and viral infections; defective lymphocyte apoptosis and activation	AD	Defects in *CASP8*, intracellular apoptosis and activation pathways
(v) Activating N-Ras defect, N-Ras ALPS	Increased CD4– CD8– T cells	Elevation of CD5 B cells	Normal	Adenopathy; splenomegaly; leukemia; lymphoma; defective lymphocyte apoptosis following IL-2 withdrawal	AD	Defect in *NRAS* encoding a GTP binding protein with diverse signaling functions, activating mutations impair mitochondrial apoptosis
(vi) IPEX, immune dysregulation, polyendocrinopathy, enteropathy (X-linked)	Lack of CD4+ CD25+ FOXP3+ regulatory T cells	Normal	Elevated IgA, IgE	Autoimmune diarrhea; early onset diabetes; thyroiditis; hemolytic anemia; thrombocytopenia; eczema	XL	Defects in *FOXP3*, encoding a T-cell transcription factor

Purine nucleotide phosphorylase (PNP) deficiency

This rare autosomal recessive disorder, which affects the purine salvage pathway and prevents normal conversion of inosine to hypoxanthine and guanosine to guanine, results in intracellular accumulations of deoxyGTP that are particularly toxic to T cells as well as distinctively low levels of uric acid in blood and urine [149]. Although T-cell function may be normal at birth, profound T lymphopenia soon develops. These patients may present with severe infections, including varicella pneumonia, and their T cells may exhibit no response to PHA or antigens consistent with $T^-B^+NK^+$ SCID, or, in some cases, a less profound and sometimes fluctuating combined immunodeficiency. They also exhibit developmental delay, hypotonia, and spasticity.

Early experience with HLA-matched related grafts was largely unsuccessful due to failure of engraftment when pretransplant conditioning was not administered [149]. However, since 1996, several patients have been successfully transplanted with matched related or unrelated HCT or cord blood grafts after myeloablative conditioning with busulfan and cyclophosphamide [150] or fludarabine [151].

However, it is important to note that although transplants of HLA-matched related and unrelated marrow as well as HLA haplotype disparate TCD grafts and cord blood grafts can correct the immunologic deficits of NP deficiency, the neurologic deficits, while potentially stabilized, are not reversed.

Combined immune deficiencies associated with defective DNA repair

Generation of T-cell receptors, immunoglobulin class switching and antibody diversity all require somatic DNA rearrangements of Variable (V) Diversity (D) and Joining (J) segments, a process which entails DNA double-strand breaks and repair by non-homologous end joining (NHEJ). As previously noted, while null mutations of recombinases 1 or 2 (RAG1/2) and Artemis induce classical SCID, hypomorphic mutations may permit limited rearrangements of T-cell receptors and class switching, resulting in Omenn syndrome or, for Artemis, common variable immune deficiencies. Recently, a series of other genes have been identified that play a critical role in NHEJ that may also induce progressively severe defects in T- and B-cell development and function, resulting in life-threatening susceptibility to infections, autoimmune cytopenias and/or EBV-induced malignancies in the first decade of life. These include null mutations in the DNA-phosphokinase CS that activates Artemis [152], mutations in the Cernunnos (or XLF) gene which encodes a protein essential for initiation of NHEJ [12], hypomorphic mutations of DNA ligase IV [13], and mutations of the NBS1 gene responsible for the Nijmegen breakage syndrome [153]. Each of these diseases is also associated with microcephaly and increased sensitivity to radiation.

Experience with transplants for these disorders is very limited. However, with reduced-intensity, fludarabine rather than alkylator-based regimens, transplants of matched related and unrelated grafts have induced full chimerism, immune reconstitution and thus far, freedom from autoimmune sequelae and lymphoid malignancies. Three patients transplanted for Cernunnos deficiency have been reported. One patient, at age 9, received an HLA-C disparate graft after conditioning with fludarabine, cyclophosphamide and ATG, and did well [154]. Two other patients who were of consanguineous parents received grafts at age 15 months from an HLA-matched sibling and achieved engraftment and reconstitution without preparative cytoreduction [155]. Of five reported patients transplanted for DNA ligase IV deficiency, three were successfully transplanted while in stable condition after fludarabine, cyclophosphamide and ATG conditioning [156]. Two others who presented with recurrent infection and a SCID-like immunodeficiency died early after transplant of EBVLPD and SOS, respectively [13]. In contrast, of six patients transplanted for immunodeficiency or a lymphoid malignancy associated with the Nijmegen breakage syndrome, five survive with reconstitution [157]. In 4/5 patients, use of a non-myeloablative regimen and a matched donor (n = 4) was associated with success. In addition, one of these patients was also successfully grafted after myeloablative conditioning with melphalan, thiotepa, and fludarabine and a T-cell-depleted HLA haplotype disparate graft. Taken together, these results indicate that disorders in this class of combined immune deficiency can be corrected particularly when fludarabine-based RIC regimens and suitably matched transplants are employed.

Cartilage–hair hypoplasia (CHH)

CHH is an autosomal recessive disorder presenting with short stature, chondrodysplasia, thin hair, and variably severe immunodeficiency. CHH is caused by mutations in the RMRP gene encoding the RNA segment of the mitochondrial RNA processing endoribonuclease [59]. RMRP, in complex with the telomerase reverse transcriptase (TERT), modulates cell proliferation. Severe deficiency results in impaired growth and maturation of T cells, and can result in a SCID-like combined immunodeficiency. Less severe variants present later in life particularly with severe varicella infection, autoimmune cytopenia, and EBV-associated lymphoid malignancies [58]. The immune deficits can be reversed by an allogeneic HCT [57]. In a European survey, HLA-matched related and unrelated marrow grafts administered after myeloablative conditioning with busulfan or melphalan and fludarabine or cyclophosphamide have induced full chimerism, correction of immune deficits, and long-term survival in 4/5 and 6/8 of the cases, respectively [158]. In contrast, three patients who received HLA haplotype disparate grafts that were administered after such myeloablative conditioning coupled with alemtuzumab fared poorly, due either to graft rejection or alloimmune cytopenias resulting from selective engraftment of donor T cells [158].

Combined immunodeficiencies with ectodermal dysplasia

These disorders are caused by X-linked mutations in the gene encoding nuclear factor κβ essential modulator (NEMO or IKK-γ) or autosomal dominant gain of function mutations in Iκβα [159,160]. These defects result in impaired activation of NF-κB in response to signals from TLRs and receptors for the cytokines IL-1, IL-6, IL-18, and TNF. This inhibits T-cell proliferation in response to exogenous pathogens and prevents the generation of memory T cells. Patients with these disorders usually present in the first 6–12 months of age with recurrent bacterial and DNA virus infections. They are also distinctively susceptible to atypical mycobacterial infections as well as chronic colitis. These patients also present with ectodermal dysplasia marked by abnormal sweat glands resulting in hypo or anhidrosis, sparse hair, and distinctive conical teeth. Eight patients with severe immune deficiencies caused by NEMO ($n = 6$) or Iκβα mutations ($n = 2$) have received transplants of HLA-matched related or unrelated marrow or PBSC, or HLA disparate cord blood or T-cell-depleted parental marrow after myeloablative conditioning with busulfan or melphalan together with cyclophosphamide or fludarabine, of whom five survive with hematopoietic and immune reconstitution [161,162]. However, unlike the CID patients with disorders of DNA repair, these patients did not regularly engraft. Even with matched transplants, three required secondary transplants after additional cytoreduction to achieve durable donor chimerism [161,162]. Furthermore, while reconstitution of T-, B-, and NK-cell function reverses their abnormal susceptibility to infection, chronic colitis, not related to GVHD, usually persists [161,162] as do the other features of ectodermal dysplasia.

Dock 8-deficient hyper IgE syndrome

The hyper IgE syndromes are a series of genetic disorders with the shared features of severe eczema and atopy, sinopulmonary infections, and elevated IgE [148]. They include Job syndrome, an autosomal disorder resulting from dominant negative mutations in STAT3, with its distinctive feature of recurrent severe staphylococcal skin abscesses [148], TYK2 deficiency, an autosomal recessive disorder with its distinctive sensitivity to disseminated BCG infections [148], and an autosomal recessive disorder caused by large deletions or mutations in the dedicator of cytokinesis 8 (Dock 8) gene [148,163,164] which result in profound defects of CD4 and CD8 T-cell activation, and impairment of differentiation of Th17 cells as well as deficits in humoral immunity [163,164]. Dock 8 deficiency is marked by a progressive combined T- and B-cell deficiency, hyper IgE, and a distinctive susceptibility to chronic and often mutilating cutaneous infections caused by molluscum contagiosum, herpes simplex, and papilloma viruses and early susceptibility to squamous cell carcinomas, cutaneous T-cell leukemia/lymphoma and HPV- and EBV-associated malignancies [163,164]. Hyper IgE syndromes associated with STAT3 and TYK2 mutations can often be controlled by antibiotics and conservative therapy. In rare cases with recurrent severe infections affecting the lung, HLA-matched allografts have been successfully applied [165].

In contrast, the prognosis for patients with Dock 8 deficiency is poor [163]. Indeed, HSCT constitutes the only approach capable of controlling or curing the disorder. To date, eight patients with Dock 8 deficiency have been reported who have received HCT from HLA-matched related or unrelated donors [166]. All but one [167] received myeloablative conditioning with busulfan/cyclophosphamide, thiotepa/melphalan/fludarabine or mel/flu and ^{90}Y anti-CD66 providing 1600 cGy to the marrow. Of these eight, one died of bacterial sepsis early on. However, five of the seven survivors are engrafted with full chimerism, immune reconstitution and clearance of viral infection and eczema. The other surviving patient who received non-ablative conditioning with 400 cGy TBI/fludarabine and cyclophosphamide is a mixed chimera whose eczema and viral infections have resolved but who still has persisting atopy and mildly elevated IgE. Strikingly, despite extensive cutaneous abnormalities pretransplant, only one patient developed GVHD which was limited to the skin and cleared rapidly with systemic steroids. Thus, HLA-matched related or unrelated HSCT can be successful in a high proportion of these patients.

CD40 ligand deficiency (X-linked hyper IgM syndrome)

One of the most extensively studied and treated CID is the X-linked hyper IgM syndrome. This disorder is caused by null mutations in the gene encoding CD40 ligand, which is essential for T cells to provide help so that B cells can form germinal centers and initiate isotype switching to generate antibodies other than IgM. Absence of CD40 ligand also compromises macrophage activation and deletion of autoreactive T cells [168]. Likely, as a consequence, these patients are susceptible to chronic infections due to viruses and intracellular microbes such as *Cryptosporidium*. They are also prone to autoimmune cytopenias [169].

Results of transplants applied to patients with hyper IgM syndrome caused by CD40 ligand deficiency have improved significantly over the last decade. For example, Gennery et al. [170] reported the European experience of transplants administered after myeloablative conditioning for X-linked hyper IgM ($n = 38$) performed from 1993 through 2002. Donors included an HLA-identical sibling ($n = 14$), a phenotypic HLA-matched family member ($n = 4$), or a matched unrelated donor ($n = 22$). Of 38 patients, 34 engrafted, and 26 patients survived, of whom 22 developed normal T-cell function and 18 generated specific antibody following vaccination. One additional patient engrafted but has poor T-cell immune reconstitution. Twelve patients (32%) died from infection which was associated with grade II–IV GVHD in six. Poor prognostic factors in this study included pre-existing liver and pulmonary disease. Reduced-intensity conditioning is now being increasingly explored. The first two patients with hyper IgM syndrome and chronic liver disease who received an unmodified HLA-matched sibling HCT following cytoreduction with low-dose busulfan, fludarabine, ATG, and CyA [171] survive >2 years post-HCT (one a mixed chimera, the other a full chimera) with normal T-cell function off supplemental IVIG.

The bare lymphocyte syndromes (BLS)

The bare lymphocyte syndromes are a set of combined immune deficiencies resulting from mutations that inhibit appropriate expression of HLA proteins on the cell surface and thereby prevent the presentation of antigenic peptides required for T-cell sensitization and both T- and NK-cell recognition of antigenic targets. Type 1 BLS is caused by mutations in the TAP1 or 2 transporter genes essential to peptide presentation by class I HLA alleles [172]; type 2 BLS are caused by mutations in genes encoding components of regulatory factor X (RFXANK, REXAP, or RFX-5) that activate the promotor controlling the transcription of HLA class II alleles [173]. The more common class II BLS are associated with CD4 lymphopenia and the absence of antigen-specific T-cell responses or the T-cell help required to generate antibodies. All patients with BLS are at high risk of severe and recurrent viral, bacterial, and fungal infections [174]. In the 1980s and 1990s HLA-matched transplants administered to patients with the bare lymphocyte syndromes were associated with high rates of transplant-related mortality due to viral infections and graft rejection with overall survival rates of 50% for matched, and 0–20% for mismatched grafts. Early series recorded graft failure rates exceeding 20–30% for HLA-matched related grafts and higher for HLA disparate transplants [175]. Recent studies that have consistently employed myeloablative conditioning with busulfan and cyclophosphamide together with ATG or alemtuzumab to deplete chemotherapy-resistant host T cells that are capable of responding to HLA$^+$ donor cells, have recorded engraftment rates of 80–100% and survival with reconstitution for 60–76% of HLA-matched related graft recipients [176]. Experience with single HLA allele disparate related and unrelated marrow and cord blood transplants has also improved. While graft failure rates for these transplants remain high, a significant proportion of these patients have engrafted following secondary transplants. In the recent multicenter experience reported by Small et al. [177] 67% of such patients were long-term survivors with immune reconstitution, including 4/7 T-cell-depleted HLA haplotype disparate graft recipients. While viral infections remain a significant cause of mortality, the proportion of patients succumbing to CMV and adenoviral infections in recent series is lower, reflecting both the introduction of more effective antiviral drugs and improved supportive care.

Familial hemophagocytic lymphohistiocytosis (HLH)

The HLH syndromes include a series of genetically determined and virus-induced disorders principally characterized by inflammatory responses involving multiple organs induced by ineffectively controlled macrophage activation, expansion of T-cell populations and abnormal cytokine production, resulting in fever, severe cytopenias secondary to hemophagocytosis, adenopathy, splenomegaly, lymphoid and histiocytic infiltration and damage to organs, particularly the liver and central nervous system, and in certain types, uncontrolled lymphoproliferative diseases [178]. Diagnostic criteria that have been established include these clinical features together with laboratory evidence of hemophagocytosis, increased levels of ferritin and soluble IL-2 receptor α or deficient NK-cell function, and metabolic disturbances such as hypofibrinogenemia, hyponatremia, and hypertriglyceridemia [178]. Five genetic forms of HLH identified to date are caused by autosomal recessive loss of function mutations in genes essential to the capacity of NK cells, CD56$^+$ NK T cells or antigen-specific T cells to form functional cytolytic synapses with target cells. These include mutations in perforin (FHL-2), and the MUNC-1 (FHL-3) and syntaxin 11 (FHL-4) proteins essential to degranulation as well as mutations affecting lysosome granule trafficking (the Chediak-Higachi syndrome gene LYST) and granule exocytosis (the Griscelli syndromes types 1–4 and the Hermansky–Pudlak syndrome) (Table 73.2) [178].

Following the initial reports in 1986 of corrections of familial HLH by Fisher et al. [179], several case reports attested to the therapeutic potential of HLA-compatible HCT in each of these disorders. Subsequently, analyses of cumulative experiences with transplants of matched related or unrelated mismatched T-cell-depleted grafts administered after myeloablative conditioning with busulfan and cyclophosphamide +/− etoposide and ATG demonstrated survival rates with disease correction in 45–58% of cases [180]. The multinational compendium of Horne et al. [181] and the AIEOP study reported by Cesaro et al. [182] detailed results for groups of 86 and 61 patients respectively that had received a standard chemotherapy induction protocol (HLH-94) with dexamethasone and etoposide prior to cytoreduction and transplant. Despite induction therapy, 43% and 60% of the patients in the two studies had active disease at time of transplant. Nevertheless, Horne et al. [181] reported 3-year survival rates of 71 and 70% for recipients of matched related and unrelated grafts, 54% for partially mismatched unrelated transplants, and 50% for haplodisparate T-cell-depleted transplants. In the AIEOP study, the 8-year survival rate for the whole group was 58% and 63% for recipients of matched unrelated or mismatched related grafts after 1999 [182]. In the large single-center experience from Paris [183], an overall 5-year survival rate of 70% was observed in recipients of unmodified HLA-matched related or unrelated grafts versus 50% for recipients of T-cell-depleted HLA haplotype disparate transplants. Engraftment rates following each type of transplant were equivalent. For recipients of haplodisparate TCD grafts transplanted in remission, the 5-year survival rate was excellent (80%). However, for patients with active disease, recipients of haplotype disparate grafts fared poorly (15% 5-year survival) particularly because of graft failure. Neurologic evidence of HLH involving CNS was also found to be a portent of poor outcome [183]. However, a more recent study suggests that transplants, including haplodisparate TCD BMT, can be effective in patients with active systemic or CNS disease, if administered early in the course of relapse [184]. In each of these studies, results for patients with defined genetic causes of HLH were equivalent to those for patients with non-familial or acquired forms of HLH.

Because of the high rates of veno-occlusive disease and toxicity-associated TRM in most series of patients transplanted for HLH after myeloablative conditioning, several groups have recently explored reduced-intensity and non-myeloablative conditioning regimens. Initial results have been very promising. Cooper et al. [185] have reported 25 patients with HLH (21 in CR) including 17 with defined genetic variants who received transplants after reduced-intensity conditioning with either melphalan (140 mg/m^2), fludarabine (150 mg/m^2 total) and alemtuzumab (for HLA-matched related or unrelated grafts), or melphalan fludarabine together with busulfan (4 mg/kg daily for 2 days) and ATG for HLA non-identical grafts. All patients engrafted; 21/25 (88%) survive in remission at a median of 3 years, including 9/11 (82%) recipients of HLA disparate grafts. Similarly, Marsh et al. [186] employed melphalan and fludarabine at the same doses together with alemtuzumab to prepare 26 patients with HLH (61% in CR) for HLA-matched or 1 allele disparate marrow grafts. All patients engrafted, although 14 patients subsequently received DLI to enhance chimerism. Nevertheless, of 26 patients, 22 (89%) were surviving in remission at a median of 654 days. Thus, this reduced-intensity conditioning is sufficient to secure consistent engraftment and control of HLH while reducing TRM and improving outcome.

X-linked lymphoproliferative diseases (X-LP)

The X-linked lymphoproliferative syndromes are caused by hemizygous mutations in the SLAM-associated protein SAP or SH2DI-A (XLP-1) or the X-linked inhibitor of apoptosis, XIAP (XLP-II) which impair cytotoxic NK cell and particularly NKT and T-cell interactions with EBV transformed cells. These defects may also augment antigen-induced apoptosis of EBV antigen-activated T cells [187,188]. This likely limits expansion of populations of virus-specific T cells resulting in susceptibility to lymphoproliferative disease.

The potential of a marrow transplant to correct XLP was first demonstrated by Filipovich et al. in 1986 [189]. Since then, most patients with XLP1 have received transplants to treat or prevent fulminant EBV infection, EBV-associated lymphomas, or other lymphoid malignancies. While experience with transplants is still limited, of 14 reported who received HLA-matched related or unrelated marrow or cord blood grafts, after myeloablative conditioning (in all but one case), 10 survive with engraftment and clearance of XLP-associated disease (reviewed in [190]).

Autoimmune lymphoproliferative syndromes (ALPS)

ALPS constitute a set of genetic disorders caused by mutations in Fas, Fas ligand, or caspase-10 or -8 that cause defective Fas-mediated apoptosis and result in lymphoproliferative disorders marked by prominent adenopathy, hepatosplenomegaly, chronic or recurrent autoimmune cytopenias and, less commonly, autoimmune disorders of other organs including the joints, kidney, liver, intestinal tract, and CNS, as well as a markedly increased risk of lymphoma and other malignancies [191,192]. These patients also have increased numbers of $CD4^-$, $CD8^-$ $TCR\alpha/\beta^+$ double negative T cells in the circulation [191,192]. The clinical disorders associated with these genetic diseases vary markedly in their severity, and are often controlled by steroids alone or in combination with mycophenolate mofetil or the MTOR inhibitor, sirolimus [192]. However, allogeneic HCTs have been used to treat lymphomas developing in these patients. Experience with transplants for the different types of ALPS is still limited. However, transplants of matched unrelated marrow administered after myeloablative and, more recently, reduced-intensity conditioning have been effective in inducing full donor chimerism and long-term remissions of disease [193]. Replacement of diseased lymphoid cells of the host by those from the normal donor also corrects the abnormalities of Fas-mediated apoptosis and reverses ALPS-associated autoimmune manifestation.

X-linked immune dysregulation, polyendocrinopathy and enteropathy syndrome (IPEX)

IPEX is a life-threatening disorder caused by loss of function mutations in Fox P3 that induce in a marked deficiency of regulatory T cells and result in uncontrolled autoimmune enteropathy, diabetes, and dysfunctions of other endocrine glands, ichthyosiform dermatitis, and autoimmune cytopenias [194]. The disorder requires sustained treatment with steroids and other immunosuppressive drugs and is often difficult to arrest. Most affected patients succumb to the disease or associated infection within the first 1–3 years of life. Early reports of HLA-matched related or unrelated HCT administered after myeloablative conditioning, including TBI or high-dose busulfan, documented a high rate of mortality due to organ toxicity or infectious complications [194,195]. However, such transplants administered after reduced-intensity conditioning such as with fludarabine, melphalan, and alemtuzumab or 400TBI and fludarabine, have achieved consistent full or sustained mixed chimerism with reconstitution of Fox $P3^+$ regulatory T-cell populations of donor origin and durable resolution of IPEX-associated autoimmune enteropathy, dermatitis, and cytopenias [196,197]. While many endocrinopathies stabilize, diabetic states antedating transplant have not improved. Nevertheless, the consistent success and long-term survival of the patients receiving HLA-compatible grafts after these reduced-intensity regimens underscore the good prognosis and curative potential of such transplants in this disease.

Wiskott–Aldrich syndrome (WAS)

Wiskott–Aldrich syndrome (WAS) is a rare X-linked disorder characterized by thrombocytopenia, immunodeficiency and eczema estimated to occur in 1 in 10 million live male births [198]. Affected individuals also have an increased risk of lymphomas, particularly EBV-LPD and autoimmune disorders [199]. The mutated gene responsible for WAS and the milder disorders of X-linked thrombocytopenia and X-linked neutropenia was discovered in 1994 by Derry and colleagues [199]. The normal gene, which maps to Xp11.22-p11.23, encodes a 501 amino acid, 53 kDa intracellular protein (WAS protein or WASp), expressed in most hematopoietic cells [199]. WASp is involved in cytoskeletal organization (reviewed in [200]) and plays an essential role in T- and NK-cell activation [198,200,201]. Over 150 unique mutations in more than 300 families worldwide have now been identified [198,202].

Although all patients with WAS are thrombocytopenic, the level of T- and B-cell immunodeficiency, and subsequent risk of autoimmune phenomena (nephropathy, vasculitis) and lymphoid malignancies can be quite variable. Zhu et al. [203] first demonstrated that the clinical heterogeneity observed in WAS patients is due to differences in the expression of WASp in lymphoid cells. Currently, patients are divided into five clinical groups on the basis of WASp expression ranging from group 1, patients with mild clinical disease associated with low levels of WASp in peripheral blood mononuclear cells to group 5 patients who lack WASp expression and have severe disease [198]. This scoring of patients, based on the pattern of WASp expression in individual patients is now used to determine which patients lacking an HLA-matched related donor should be treated with supportive care alone, and which should be early candidates for HCT from alternative donors [198]. Several other studies have also shown a strong phenotype association with genotype in this disorder. For example, Jin et al. [204] evaluated the correlation of genotype with phenotype in 262 patients from 227 unrelated families with WAS/XLT followed in two centers, one in Seattle, the other in Italy. The best predictor of clinical manifestations was determined by WASp expression. The majority of patients in this study who had no detectable WASp in lymphoid cells had deletions or insertions which resulted in frameshift, non-sense, or splice site mutations. In contrast, 74% of patients with XLT had missense mutations, and low levels of WASp.

HCT for Wiskott–Aldrich syndrome (WAS)

In 1968, Bach et al. [83], reported correction of the immunologic abnormalities associated with WAS following HLA-matched sibling transplantation. However, despite high-dose CY, this patient remained thrombocytopenic. In 1978, Parkman et al. [205] corrected both the immunologic and hematologic defects in a child with WAS by administering an HLA-matched marrow graft after myeloablative cytoreduction with TBI, procarbazine, and ATG, and hypothesized that myeloablation as well as immunosuppression were required to provide "space" for hematopoietic progenitor cells to develop. Subsequently, Kapoor et al. [206] demonstrated that conditioning with BU (8 mg/kg) and CTX (200 mg/kg) also induced full hematopoietic chimerism, correcting both the lymphoid and platelet defects in a series of children with WAS. Subsequent single-center studies of HLA-identical related BMT [207–210] have recorded long-term survival rates ranging from 80–100%. Of 65 children with WAS reported between 1968 and 1997, 57 (87%) were surviving long term after HLA-matched BMT [211].

For patients without an HLA-matched sibling, transplants from closely matched unrelated donors currently also provide excellent results. In a series of 30 patients with WAS who received an unrelated unmodified BMT prior to July 1994, Filipovich reported an overall actuarial survival of 67% [98]. Analysis of these transplantation results demonstrated that children <2 years of age at the time of transplant had a much better prognosis with 21 of 23 surviving (actuarial survival at 3 years of 91%). Acute grade II–IV GVHD occurred in 50% of patients, with the highest incidence and severity observed in patients >5 years of age at HCT. In 2001, Filipovich et al. [212] summarized the results of 170 transplants reported to the International Bone Marrow Transplant Registry and/or the National Marrow Donor Registry (1968–1996) and compared 58 patients transplanted from HLA-matched siblings, 48 from other relatives, and 67 patients from unrelated donors. Transplant outcome differed according to donor type with the probability of 5-year survival of 87% (74–93%) with an HLA-identical sibling donor, 52% (37–65%) with other related donors, and 71% (58–80%) with unrelated donors. For recipients of unrelated HCT, the best outcomes were again observed in patients transplanted at less than 5 years of age.

Recent results of unrelated grafts have significantly improved, likely reflecting the introduction of improved DNA sequence-based HLA matching, broader access to donors, less toxic and better monitored myeloablative conditioning, and better supportive care. Pai et al. reviewed 16 unrelated HCT for WAS performed at the University of Brescia from 1990 through 2005 [209] of whom 13 survive (81.2%) a median (range) of 6 (0.6–9) years post-HCT. Similarly, Kobayashi et al. [210] reported that 80% of WAS patients in Japan who received an unrelated HCT ($n = 21$) survive and 75% are disease-free [210]. Prognosis was again poorer in patients who were transplanted >5 years of age and those who received cytoreduction with a regimen other than BU/CY +/− ATG.

In a recent multinational review of the results of transplants for Wiskott–Aldrich syndrome between 1980 and 2009, 91 received matched unrelated grafts, almost all after Bu/CTX+ATG. For patients grafted between 1980 and 1999 versus ≥2000, survival rates at ≥5 years were 77% versus 90% [213]. Of those transplanted at ≤5 years of age, 90% are long-term survivors compared to 73% of those transplanted at >5 years of age. Nevertheless, the improvement in results for older patients is striking when compared to survival rates reported in earlier transplant series [98,210,212].

Cord blood transplants have been only recently introduced to the treatment of patients with Wiskott–Aldrich syndrome. However, since 2003, several centers have explored this approach [210,214]. In the compendium of patients transplanted for WAS in Japan, 12/15 (80%) recipients of unrelated cord blood grafts administered after Bu/CTX +/− ATG were surviving at >5 years [210]. Similarly, in the multinational analysis reported by Moratto et al. [213], of 24 patients treated with UCB since 2000, 82% were long-term survivors.

Results of HLA haplotype disparate TCD grafts from related donors which have been applied to patients lacking an HLA-compatible related or unrelated donor have also markedly improved over the last 10 years. Early experiences with such transplants were marked by unacceptably high rates of graft failure and mortality due to GVHD and infection. As a result, long-term survival rates in early single and multicenter series ranged from 16–55% [90,207,210–212,215]. However, with the introduction of methods for adequately depleting T cells from PBSC, high doses of progenitor cells can be given without need of post-transplant immune suppression to prevent GVHD. As a result, consistent engraftment can now be achieved. Furthermore, the introduction of drugs and immunotherapies has provided increasingly effective approaches to prevent or treat serious EBV, CMV, and adenoviral infections in the post-transplant period. Reflecting these advances, 5-year survival rates reported in the recent international collaborative study reported by Moratto et al. [213] have significantly improved from the 52.2% rate observed for patients transplanted from 1980–1999 to 91.7% for patients transplanted between 2000 and 2009. Indeed, in this report, results of HLA haplotype disparate TCD grafts administered between 2000 and 2009 were equivalent to those achieved with unmodified transplants from matched unrelated donors.

Late complications in patients transplanted for Wiskott–Aldrich syndrome

Experience with allogeneic HCT for WAS dates to 1968, permitting an assessment of the influence of a successful graft on the long-term complications of WAS, particularly their susceptibility to infections by polysaccharide encapsulated bacteria, hemorrhagic EBV lymphomas, and other neoplasias and autoimmune disorders.

Results of single and multicenter trials indicate that immune reconstitution with donor cells post-transplant has reduced the risk of bacterial infections to that of normal peers in most patients transplanted for WAS. An exception, however, is the patient splenectomized prior to transplant. Such patients remain at risk of life-threatening pneumococcal, meningococcal, or other pyogenic infection if they do not adhere to penicillin prophylaxis [213,216]. While patients cytoreduced with myeloablative regimens usually experience sustained correction of thrombocytopenia, 9% of patients, specifically those who achieved only mixed chimerism, have remained thrombocytopenic, and may ultimately require a second graft [208,213]. While patients with WAS are at risk for EBV-LPD early post-transplant, long-term risk of malignancies is approximately 5%, a rate comparable to that of individuals receiving HSCT for other indications [208,213].

Conclusion

Allogeneic HCT from a normal matched related donor remains the treatment of choice for each of the different genetic variants of SCID. Currently, HLA-matched unmodified grafts from unrelated donors administered with post-transplant drug prophylaxis to prevent GVHD and rigorously T-cell-depleted HLA-haplotype disparate-related transplants administered without post-transplant GVH prophylaxis also yield good results, with long-term disease-free survival rates of approximately 70–74% overall and over 90% for patients transplanted in the first 3 months of life. The relative advantages of each approach will require careful prospective analyses of large series. Certain types of SCID, particularly, ADA-deficient SCID and NK^+ variants as well as "leaky" forms of SCID, including Omenn syndrome exhibit graft resistance and may require preparative cytoreduction, particularly when the donors are other than HLA-matched siblings. Inclusion of myelosuppressive alkylating agents such as busulfan, treosulfan, thiotepa, or melphalan is also preferable to secure consistent engraftment of donor B cells and NK cells as well as T cells in these variants and thereby achieve reconstitution of both cell-mediated and humoral immunity.

For patients with other combined immunodeficiency diseases and Wiskott–Aldrich syndrome, preparative cytoreduction with a myelosuppressive agent together with immunoablation with cyclophosphamide or fludarabine is required to achieve consistent engraftment and reconstitution. For these indications, transplants of unmodified HLA-matched related and unrelated HCT have thus far been associated with better outcomes than T-cell-depleted HLA-disparate grafts. Certain of these disorders, particularly the bare lymphocyte syndrome associated with HLA class II deficiency, exhibit excessive rates of graft failure despite use of these regimens. For the future, development of well-tolerated preparative regimens and transplant approaches that secure consistent engraftment and full chimerism is a high priority. Introduction of selected cytokines or specific cell therapies at the time of transplant may also foster full engraftment and enhance recovery of immune function

A separate chapter on gene therapy details approaches currently being evaluated in clinical trials to transduce hematopoietic stem calls with vectors encoding normal genes to correct several life-threatening disorders of immunity and hematopoiesis. Treatment with genetically modified autologous hematopoietic stem cells has recently shown great promise in the treatment of children with ADA-deficient SCID when administered after myelosuppression with busulfan. However, the proportion of patients achieving full reconstitution is thus far not different from that currently achievable with matched unrelated or T-cell-depleted HLA non-identical grafts [69]. Longer follow-up will be required to determine whether and to what degree gene therapy will supplant HCT as a treatment of choice for specific variants of SCID such as ADA deficiency. For patients with X-linked IL-2R γc-deficient SCID and Wiskott–Aldrich syndrome, gene-modified autologous HCT can reconstitute T- and, in some cases B-cell immunity. Furthermore, this approach can induce production of platelets in patients with Wiskott–Aldrich syndrome that are normal in number and function. However, the risk of leukemic transformation of genetically corrected cells has been prohibitively high. In the future, alternative vectors and strategies permitting site-specific genetic corrections may eliminate the risk of late leukemic transformation of transduced cells, and secure a role for gene therapy in these patients.

CHAPTER 74

Hematopoietic Cell Transplantation for Storage Diseases

Joseph Rosenthal
Pediatric Hematology/Oncology, City of Hope Medical Center, Duarte, CA, USA

Introduction

Lysosomal storage disorders (LSDs) are a large group of about 50 rare and genetically inherited metabolic disorders arising from single-gene defects that often involve a lysosomal hydrolytic enzyme or vital peroxisomal function, causing devastating systemic diseases that can affect multiple organs (Tables 74.1–74.3). These conditions may be caused by defective membrane proteins, errors in enzyme targeting or defective function of enzyme activators. These changes cause pathologic accumulation of undegraded macromolecules inside lysosomes, which represents the typical hallmark of these diseases and results in complex clinical phenotypes. Owing to the housekeeping nature and ubiquitous expression of lysosomal hydrolases, these pathologies are multiorgan, multisystemic, and usually life-threatening. Clinical manifestations tend to worsen as more waste substrate accumulates over time, with symptoms varying in severity from relatively mild to severe somatic and rapidly progressing neurologic manifestations [1,2]. The precise mechanisms by which storage materials disturb cellular functions are not fully understood; alterations occurring in many cellular processes, such as autophagy, intracellular calcium homoeostasis, signaling pathways, trafficking, inflammation and oxidative stress response, have been found to contribute to the pathologic progression. Although individually rare and with a low incidence in most populations, taken together LSDs account for about one patient in every 5000–9000 live births.

For the past three decades, hematopoietic cell transplantation (HCT) has been used as effective therapy for selected inborn errors of metabolism (IEM), mainly lysosomal storage diseases and peroxisomal disorders. The main rationale for HCT in IEM is based on the provision of correcting enzymes by donor cells within and outside the intravascular compartment. The ultimate goal of HCT is to achieve normal or near-normal quality of life by preventing further neurologic and developmental deterioration, which characterize these conditions. Detailed studies suggesting that HCT is indicated for carefully selected cases are available only for Hurler syndrome, X-linked adrenoleukodystrophy (X-ALD), and infantile Krabbe disease. Improvement of transplantation techniques and alternative therapies may change the recommended indications for HCT in IEM. A recent example of emerging transplantation techniques is the fast availability of unrelated cord blood transplants (UCBT). UCBT [3–5] makes HCT feasible in patients with rapidly progressive neurologic diseases. The rapid and easy access to umbilical cord blood units has improved the ability to move forward with HCT, shortly after diagnosis and before irreversible damage has occurred. Conversely, the success of enzyme replacement therapy (ERT) in patients with a moderate/good clinical condition generated an interest in employing ERT prior to or during HCT in patients with poor clinical condition [6,7]. Autologous HCT with genetically modified cells and mesenchymal stem cell infusions constitute emerging techniques that may, potentially, halt the progression of the disorder after successful cell therapy. Improvement in HCT techniques and novel stem cell sources will continue to impact the safety and efficacy of this therapy as well as expand the list of indications. A good functioning worldwide registry would be necessary to measure the effects of the procedures performed in more detail.

HCT for storage diseases

Why does HCT work?

Lysosomes are cellular organelles that contain hydrolytic enzymes; peroxisomes are subcellular organelles catalyzing metabolic functions primarily related to lipid metabolism. In 1968, Fratantoni and Neufeld established the concept of transferable lysosomal enzymes through metabolic cross-correction of defects in co-cultured fibroblasts of patients with Hurler and Hunter syndromes [8]. Metabolic correction of lysosomal storage diseases is due to the mannose-6-phosphate receptor-mediated endocytosis of secreted enzyme, or by direct transfer of enzyme from adjacent cells [1]. It is likely that both mechanisms occur following HCT (Figure 74.1). Variability in receptor-mediated enzyme endocytosis in various cells and tissues could affect hydrolase uptake after HCT. For example, monocytes and macrophages have receptors for *N*-acetylglucosamine and mannose; glial cells have receptors for sialic acid. As an example, X-ALD is a peroxisomal disorder of very long chain fatty acid (VLCFA) β-oxidation. The likely mechanism by which HCT halts cerebral demyelination is perhaps threefold: immunosuppression, replacement with metabolically normal cell populations leading to decreased perivascular inflammation, and metabolic correction. The impact of normalizing VLCFAs in plasma is unclear.

A critical question in HCT for storage diseases with central nervous system (CNS) involvement is whether donor-derived cells enter the CNS and achieve metabolic correction or halt inflammation. Microglia are mononuclear phagocytes in the CNS, which are hematopoietically

derived. They account for 5–10% of non-neuronal cells in brain. Activated microglia participate in antigen presentation, inflammatory responses, infection, and CNS injury. In humans, repopulation with donor-derived microglia can take a year. The kinetics of microglial replacement after HCT is slower than that of other tissue macrophages (e.g., alveolar macrophages or Kupffer cells). This observation explains, in part, the inability of HCT to stabilize effectively the CNS and neurologic aspects of a rapidly progressing disorder.

History

On April 8, 1980, a 9-month-old boy received the first bone marrow transplant for Hurler syndrome [9]. Despite genotype analysis revealing homozygous W402X mutations indicative of severe Hurler syndrome (mucopolysaccharidosis IH [MPS IH]) phenotype, the patient had fully engrafted with maternal marrow, and has stable, normal intelligence [9]. In 1982, the first child with Maroteaux-Lamy syndrome, a 13-year-old girl, was successfully transplanted from her human leukocyte antigen (HLA)-matched, enzymatically normal sister, and experienced resolution of hepatosplenomegaly and normalization of cardiopulmonary function [10]; she survives and functions independently. In the late 1980s and into the 1990s, successful transplants were performed for each of the leukodystrophies, including cerebral X-ALD [11], globoid cell leukodystrophy (GLD) [12], and metachromatic leukodystrophy (MLD) [13]. In the mid-1990s to the mid-2000s, the first large multicenter reports for HCT were published on Hurler syndrome [14–16] and cerebral

Figure 74.1 Transport of a lysosomal enzyme in a normal cell and correction of storage in the cell of a patient with mucopolysaccharidosis. The mannose-6-phosphate-recognition signal is added to the lysosomal enzyme precursor in the late Golgi compartments, where enzyme modified by mannose-6-phosphate binds to mannose-6-phosphate receptors. The enzyme–receptor complex is packaged into a transport carrier vesicle and delivered to early endosomes, in which low pH promotes the dissociation of the enzyme from the receptor. The enzyme is then delivered to the mature lysosome, and the mannose-6-phosphate receptor is recycled to the Golgi apparatus. A small amount of the mannose-6-phosphate-modified enzyme escapes capture by the mannose-6-phosphate receptors and is released into the extracellular space. This enzyme can be recaptured by binding to a mannose-6-phosphate receptor in a clathrin-coated pit on the cell surface. In a patient who has undergone hematopoietic stem cell transplantation, enzyme released from a donor-derived cell can be taken up by a mucopolysaccharidosis cell, which corrects aberrant glycosaminoglycan storage. X-ALD [17]. Sources of hematopoietic cells for transplantation included bone marrow [12,13,17], peripheral blood [18], and umbilical cord blood (UCB) [17,19,20]. In addition to high-dose regimens, reduced-intensity conditioning regimens were employed effectively [18]. Successful use of combination therapy, ERT, and HCT for patients with Hurler syndrome has been described [6,7]. Finally, participants in the field have recognized the importance of a comprehensive approach to caring for these patients, which is described later.

General considerations

The following elements are critical to the success of HCT in treating patients with storage disorders: a multidisciplinary and multispecialty approach to evaluation and follow-up; careful attention to optimizing HLA typing, hematopoietic cell source selection; the risks and benefits of high-dose versus reduced-intensity conditioning regimens, supportive care measures, and long-term post-HCT evaluations. Several sets of evaluation and follow-up guidelines are provided later in this chapter (Tables 74.4 and 74.5).

Mucopolysacharidoses (MPS) and mucolipidoses (ML)

In this section, MPS disorders (Hurler, Hurler-Scheie, Scheie, Hunter, Sanfilippo, Morquio, Maroteaux-Lamy, and Sly) and mucolipidoses (ML; I-cell disease and pseudo-Hurler polydystrophy) will be presented and discussed (Table 74.1).

The MPS diseases are a group of lysosomal storage disorders caused by deficiency of degradative enzymes of glycosaminoglycans

Table 74.4 Guidelines for the pre-hematopoietic cell transplantation (HCT) evaluation (section A) and post-HCT (section B) follow-up of patients with mucopolysaccharide, mucolipidosis, and glycoprotein metabolic disorders

Section A	**Pre-HCT**
Neurology	Examination including assessment for signs or symptoms of hydrocephalus in patients with Hurler syndrome
Neuropsychology	Test of cognitive ability according to age and developmental level, e.g., Mullen Scales of Early Learning to obtain Early Learning composite or WISC III Language assessment to obtain receptive and expressive language scores Vineland Adaptive Behavior Scales
Neuroradiology	MRI of brain and upper cervical spine with attention to the odontoid process in patients with Hurler syndrome
Cardiology	Echocardiogram, EKG
Pulmonology	Chest X-ray (posteroanterior and lateral) Polysomnogram
Audiology	ENT as needed for placement of tubes Brainstem auditory evoked response if requested by audiology department
Ophthalmology	Routine evaluation and if possible ocular pressures in patients with Hurler syndrome
Genetic counseling	
Neurophysiology	Electrophysiology studies (EMG) with surface electrodes to evaluate for carpal tunnel syndrome if clinically indicated in patients with Hurler syndrome
Occupational, physical, and speech and language therapy	Assessment and therapies as needed, of particular importance in children with Hurler syndrome
Donor studies	Donor enzyme activity level, if possible, in addition to infectious disease markers
Molecular biology studies	On admission to hospital, consider obtaining blood samples for DNA (e.g., mutation analysis, pharmacogenomics)
Lumbar puncture	If there are clinical concerns about possible, significant increased intracranial pressure, a lumbar puncture with determination of opening and closing pressures may be performed with determinations of cerebrospinal fluid glucose and protein in patients with Hurler syndrome
Section B	**Post-HCT**
Blood and marrow transplant (BMT) team	BMT physician, neurologist, neuropsychologist or developmental pediatrician, cardiologist, pulmonologist/sleep disorder specialist, endocrinologist, audiologist, ophthalmologist, occupational and physical therapist, speech and language therapist, advanced practice nurse, nurse coordinator, social worker; others as needed, including occupational and physical therapists
Neurology	Examination
Neuropsychology	Test of cognitive ability according to age and developmental level, i.e., Mullen Scales of Early Learning (Early Learning Composite), or Stanford Binet Intelligence Scale (Composite Score), or Wechsler Preschool and Primary Scale of Intelligence (Full Scale IQ) Language assessment to obtain receptive and expressive language scores Vineland Adaptive Behavior Scales
Neuroradiology	MRI of brain and upper cervical spine (attention to odontoid process)
Cardiology	Echocardiogram EKG
Pulmonology	Chest X-ray Consider follow-up polysomnogram as clinically indicated
Audiology	ENT as needed for placement of tubes Brainstem auditory evoked response if requested by audiology department
Ophthalmology	Electroretinogram
Orthopedic surgery	Orthopedic evaluation of spine, hips, and knees, and hand surgery assessment for carpal tunnel syndrome
Endocrinology	Growth hormone stimulation test Free thyroxine Thyroid-stimulating hormone levels Dual-energy X-ray absorptiometry scan Bone age X-ray
Neurophysiology	Electrophysiology studies (EMG) with surface electrodes to evaluate for carpal tunnel syndrome
Occupational, physical, and speech and language therapy	Assessment and therapies as needed
Engraftment and chimerism studies	Variable number of tandem repeat or XY fluorescence in situ hybridization studies and enzyme level (days +21–30, +60, +100, +6 months, +1 year, and yearly post-HCT thereafter as needed

EKG, electrocardiogram; EMG, electromyelogram; ENT, ear, nose, and throat; MRI, magnetic resonance imaging.

(GAGs) [1], which include heparan, dermatan, keratan, and chondroitin sulfates, that individually or in combination accumulate intracellularly, leading to cellular dysfunction. These GAGs are usually excreted in urine and can be detected by initial diagnostic screening tests. Genes and their complementary DNAs (cDNAs) encoding most of the enzymes have been cloned, leading to characterization of their primary structures, production of recombinant enzymes, and elucidation of disease-causing mutations. MPS disorders, their genetics and respective enzymes, incidence and carrier frequencies, and treatment options are presented in Table 74.1. All of the MPS and ML disorders are autosomal recessive in their inheritance except for Hunter syndrome (X-linked). ML II (I-cell) and ML III (pseudo-Hurler polydystrophy) are related, rare genetic diseases in which there is abnormal lysosomal enzyme transport in cells of mesenchymal origin. Newly synthesized lysosomal enzymes are secreted into the extracellular medium rather than being targeted correctly to lysosomes. Affected cells show dense storage material-filled inclusions; lysosomal enzymes are present at elevated levels in serum and body fluids of affected patients [21].

Shared clinical features among the MPS disorders include progressive, multiorgan system involvement, organomegaly, dysostosis multiplex, and facial dysmorphia. Hearing, vision, respiratory, and cardiovascular function are often affected. Severe cognitive

Table 74.5 Guidelines for the pre-hematopoietic cell transplantation (HCT) evaluation (section A) and post-HCT (section B) follow-up of patients with leukodystrophies

Section A	**Pre-HCT**
Neurology	Examination
Neuropsychology	Age-appropriate battery of neuropsychologic tests, i.e., Wechsler Preschool and Primary Scale of Intelligence (WPPSI-revised) and Wechsler Intelligence Scale for Children III (WISC-III) Wechsler Adult Intelligence Scale III to obtain: • Full Scale IQ Score • Verbal IQ Score • Performance IQ Score Other testing to measure school achievement, language, visual perception, attention, memory, motor function, executive function. and behavior Vineland Adaptive Behavior Scales
Neuroradiology – cerebral X-ALD	MRI of brain including contrast agent (gadolinium) with severity score determinations (Loes Score [63]); Magnetic resonance spectroscopy if available and deemed to be potentially informative
Neuroradiology – GLD [12] and metachromatic leukodystrophy	MRI of brain
CSF	Examination of CSF (including CSD protein): may be informative in patients with advanced disease at HCT to evaluate status of blood–brain barrier disruptions (i.e., degree of CSF protein elevation; e.g., in infants with GLD, CSF protein levels of 500–600 mg/dL can be seen)
Pulmonology	Chest X-ray
Ophthalmology	Assessment as needed
Endocrine	To assess treatment of adrenal insufficiency (i.e., dosing of hydrocortisone) in boys with X-ALD; routine assessment of all patients for thyroid function, progress toward puberty, growth, and development
Neurophysiology	Electrophysiology studies (EMG): a long-term evaluation in boys transplanted for cerebral X-ALD who are reaching the age at which they are at risk for developing AMN, i.e., approximately ≥20 years of age. The question of whether such men will develop AMN is unanswered
Occupational, physical, and speech and language therapy	Assessment and therapies as needed
Section B	**Post-HCT**
Blood and marrow transplant (BMT) team	BMT physician, neurologist, advanced practice nurse, nurse coordinator, social worker; others as needed, including occupational and physical therapists
Neurology	Examination
Neuropsychology	Age appropriate battery of neuropsychologic tests, i.e., Wechsler Preschool and Primary Scale of Intelligence (WPPSI-revised) and Wechsler Intelligence Scale for Children III (WISC-III) Wechsler Adult Intelligence Scale III to obtain: • Full Scale IQ Score • Verbal IQ Score • Performance IQ Score Other testing to measure school achievement, language, visual perception, attention, memory, motor function, executive function, and behavior Vineland Adaptive Behavior Scales
Neuroradiology – cerebral X-ALD	MRI of brain including contrast agent (gadolinium) with severity score determinations (MRI severity or Loes Score [63]); recommended minimum number of examinations – approximately 2–3 months post-HCT to evaluate for resolution of gadolinium enhancement (hallmark of active demyelination in cerebral X-ALD) and at 1 year post-HCT to evaluate severity score at time when stabilization has been achieved [64]. Subsequent brain MRIs as clinically indicated Magnetic resonance spectroscopy if available and deemed to be potentially informative
Neuroradiology – GLD and MLD	MRI of brain at 1 year post-HCT and annually, if clinically indicated, until stable myelination is demonstrated
CSF	Examination of CSF (including CSD protein): may be informative in patients with advanced disease at HCT to evaluate status of blood–brain barrier disruptions (i.e., degree of CSF protein elevation; e.g., in infants with GLD, CSF protein levels of 500–600 mg/dL can be seen)
Pulmonology	Chest X-ray
Ophthalmology	Assessment as needed
Endocrine	To assess treatment of adrenal insufficiency (i.e., dosing of hydrocortisone) in boys with X-ALD; routine assessment of all patients for thyroid function, progress toward puberty, growth, and development
Neurophysiology	Electrophysiology studies (EMG): a long-term evaluation in boys transplanted for cerebral X-ALD who are reaching the age at which they are at risk for developing AMN, i.e., approximately ≥20 years of age. The question of whether such men will develop AMN is unanswered
Engraftment and chimerism studies	Patient's variable number of tandem repeats and appropriate enzyme levels (days +21–30, +60, +100, +6 months, +1 year, and yearly post-HCT thereafter); follow-up evaluation of VLCFA has been discontinued as published studies showed a 55% reduction in these levels after HCT but not complete normalization [66]. VLCFA levels do not appear to have any clinical significance or correlation with disease activity or clinical status

AMN, adrenomyeloneuropathy; CSF, cerebrospinal fluid; EMG, electromyogram; GLD, globoid cell leukodystrophy; ML, metachromatic leukodystrophy; MRI, magnetic resonance imaging; VLCFA, very long chain fatty acid; X-ALD, X-linked adrenoleukodystrophy.

deficits with developmental delay are observed in Hurler (MPS IH), the severe phenotype of Hunter (MPS IIA), and Sanfilippo syndromes (MPS III) [1].

HCT represents an effective therapy with the longest clinical experience for selected MPS disorders. MPS and ML disorders that can benefit from HCT include Hurler (MPS IH), Maroteaux-Lamy (MPS VI), and Sly (MPS VII) syndromes, as well as I-cell disease (ML II). On the other hand, either limited or lack of effectiveness of HCT in benefiting the CNS and/or the skeletal system has significantly dampened enthusiasm for transplant in patients with Hunter (MPS II), Sanfilippo (MPS III), and Morquio (MPS IV) syndromes (Table 74.1).

MPS DISORDERS FOR WHICH HCT CAN BE BENEFICIAL: MPS I, MPS VI, AND MPS VII

Hurler (MPS IH), Hurler-Scheie (MPS IH/S), and Scheie syndromes (MPS IS)

Epidemiology, molecular biology, and etiology

MPS I is an autosomal recessive lysosomal storage disorder that is caused by deficient enzyme activity of α-L-iduronidase (IDUA), leading to lysosomal accumulation of GAGs in multiple tissues throughout the body. With an overall prevalence of 1 in 100,000 live births [22] and significant variability in presentation, diagnosis of MPS I in all its forms poses a true challenge. The initial diagnosis is primarily based on physician recognition of signs and symptoms. Deficient IDUA activity and excess urinary GAG excretion are seen in all patients, but do not accurately predict disease severity or form [22]. Most known disease-causing mutations (over 100 to date) are individually unique ("private") and uncharacterized.

Clinical description

MPS I is a chronic, progressive disease affecting the heart, eyes, bones, joints, respiratory system, facial appearance, viscera, and often the CNS. It has historically been classified clinically into three syndromes based on age of onset, rapidity of progression, and presence and degree of cognitive involvement [1]. Hurler syndrome, also known as MPS IH, describes patients with the most severe form of MPS I, with signs and symptoms typically appearing in infancy and a median age of death of 6.8 years when untreated. Patients with Scheie syndrome, MPS IS, present later in childhood and demonstrate slower symptom progression with preservation of cognition and survival into adulthood. Hurler-Scheie, MPS IH/S, describes an intermediate form with no or mild cognitive impairment and death usually occurring in adolescence or early adulthood when untreated. Patients with Hurler-Scheie and Scheie syndromes have also been referred to as having attenuated MPS I. Collectively, these forms represent different degrees of severity along a disease spectrum without strict clinical, biochemical, or molecular diagnostic criteria in place to differentiate them.

Hematopoietic cell transplantation for MPS I

Since the first report of successful reversal of clinical features of Hurler syndrome and improvement in biologic markers after HCT in one infant with Hurler syndrome [9], hundreds of patients with MPS IH and MPS IH/S have been transplanted. Large HCT experiences with allografts from related, unrelated and cord blood units from both related and unrelated donors [15,22,23] have provided guidance for patient selection and timing of HCT, and a realistic assessment of the effects of HCT on various organs and tissues in MPS IH and MPS IH/S, as well as neurocognitive function (Figure 74.2). While it is difficult to provide a precise estimate of long-term engrafted survival for Hurler HCT patients, the likelihood is as high as 80–85% using bone marrow or UCB (Figure 74.3) [19,23].

The decision on whether to proceed with HCT for patients with Hurler syndrome is a complex one. Factors include the child's neurocognitive and developmental status with emphasis on the potential for growth, the presence or absence of hydrocephalus with or without a ventriculoperitoneal shunt, and a history of pulmonary and airway complications such as frequent pneumonias, chronic hypoxia, sleep apnea, and cardiac failure. It is imperative that a comprehensive pre-HCT evaluation be performed and that detailed information be provided to families with particular attention to disease aspects that are typically resistant to the beneficial effects of HCT, such as skeletal abnormalities, some ocular and auditory features, and cardiac aspects. Long-term, coordinated, comprehensive monitoring not only for late effects from HCT (see Chapter 105), but also for disease-specific aspects, should be performed in close collaboration with educators and therapists (e.g., physical, occupational, speech, and language) (Table 74.4).

With successful donor-derived engraftment, MPS IH, Hurler syndrome, patients can experience favorable long-term HCT

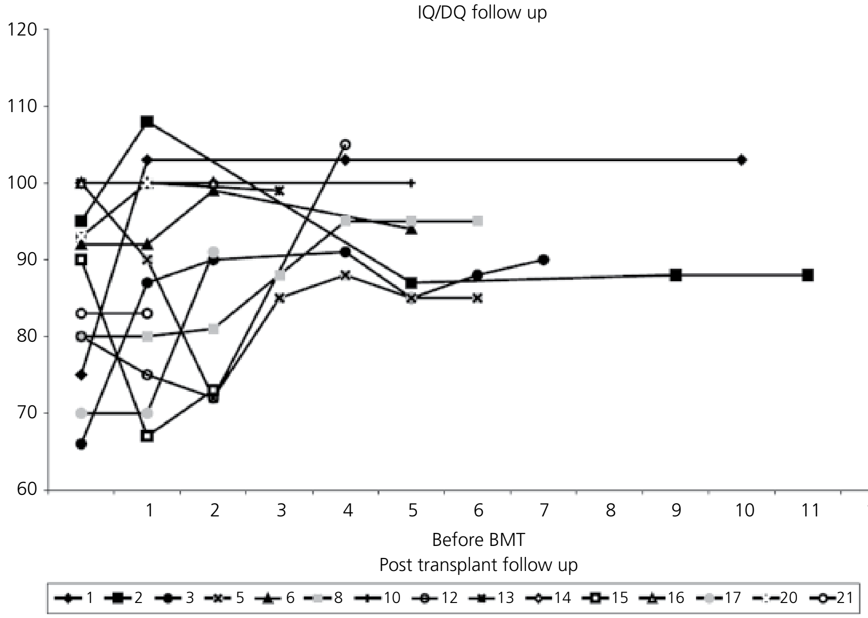

Figure 74.2 Neurocognitive function as measured by intelligence or developmental quotients (IQ or DQ) in 15 patients with Hurler syndrome before and after hematopoietic cell transplantation. BMT, bone marrow transplantation. Source: Souillet et al. 2003 [23]. Reproduced with permission of Nature Publishing Group.

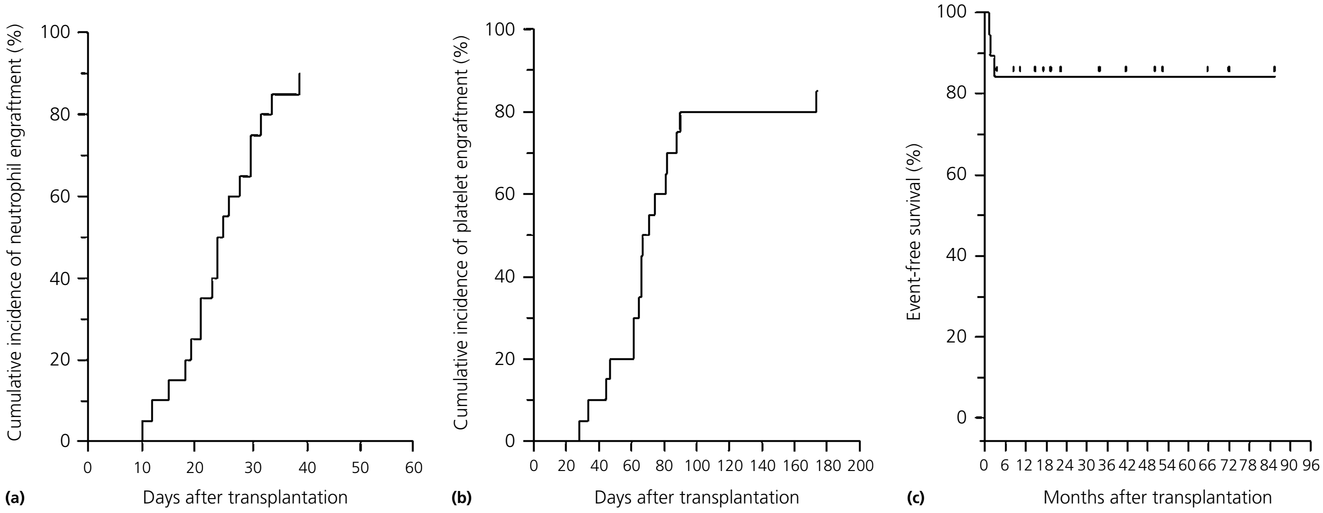

Figure 74.3 Cumulative incidence of neutrophil (a) and platelet (b) engraftment after cord blood transplant, and Kaplan–Meier estimates of the probability of event-free survival (c). In (a), myeloid engraftment was defined as an absolute neutrophil count of at least $500/\text{mm}^3$ on three consecutive days. The one patient who remained aplastic after the first cord blood transplant received a second cord blood transplant on day +63. Myeloid engraftment occurred on day +26 after the second transplant. In (b), platelet engraftment was defined by a platelet count of at least $50{,}000/\text{mm}^3$ without need for transfusion for at least 7 consecutive days. In (c), event-free survival was defined by survival with full (>99%) donor chimerism. Tick marks indicate the most recent follow-up visit for each patient. Source: Staba et al. 2004 [19]. Reproduced with permission of the Massachusetts Medical Society.

outcomes. These outcomes include stabilization of the CNS with preservation of neurocognitive function, and motor development within the normal range and capacity for independence in activities of daily living. Careful neuropsychologic and neuroradiologic assessments are needed [24–26].

When performed early in the disease course, HCT can improve metabolism and clearance of GAGs in the highly perfused visceral organs, such as the liver, spleen, adenoid, tonsils, heart, and lungs. A major reduction of the hepatosplenomegaly as well as relief of the obstructive airway symptoms, including persistent rhinorrhea and obstruction of the upper airways, is seen in all patients within the first 3–6 months after HCT [16,23,27]. Myocardial muscle function is stabilized or improved, and coronary artery patency has been demonstrated up to 14 years after HCT [28]. The long-term outcome of cardiac valvular thickening and insufficiency require continued monitoring. Furthermore, HCT helps preserve intellectual function and prevent manifestations of the classic severe Hurler phenotype with a relatively low risk of progressive cognitive deterioration. This has been achieved only when HCT is performed early in life and before cerebral damage has occurred [14–16,23,27,29]. Significant correlations, between the age at HCT and the slope of the cognitive development after HCT (−0.64; $p < 0.03$ and −0.51; $p = 0.01$), as well as the baseline Mental Development Index (MDI) and slope of the cognitive development after HCT (0.76; $p < 0.05$ and 0.77; $p = 0.0002$), have been documented in MPS IH patients [14,15] indicating that both a younger age at HCT and a higher baseline MDI are associated with better cognitive trajectories after HCT. Therefore, some authorities had suggested that HCT should only be indicated in MPS IH patients under the age of 2 years and with no more than minimal cognitive impairment (MDI $\geq$ 0.70). However, as the neurocognitive outcome of MPS IH patients older than 2 years at HCT or with a baseline MDI below 70 varies considerably [14–16,26], these contraindications must be used with caution [16]. The neurocognitive situation before HCT may be difficult to evaluate, especially in younger patients or when hearing loss is present. In addition, HCT may still be indicated after 2 years of age in those patients who present with a slightly milder phenotype. Therefore, the decision about SCT must be made on an individual basis.

Some disease features show less favorable responses due to poor penetration of laronidase into the relevant tissue. Principal among these are skeletal abnormalities also known as dysostosis multiplex. Successfully transplanted children often require major orthopedic surgical procedures for genu valgum, acetabular hip dysplasia, kyphoscoliosis, carpal tunnel syndrome, and trigger digits by 6 years of age. Orthopedic aspects of MPS disorders were the subject of a consensus conference held in Manchester, United Kingdom, in 2003 (Table 74.6). Interestingly, upper cervical spine stabilization has occurred long term in many donor-engrafted Hurler patients [30].

Cell source for HCT in patients with MPS I

Since the first bone marrow transplantation in a child with MPS IH in 1981, approximately 500 MPS patients have been transplanted using a variety of donor sources, including bone marrow (BM) or peripheral blood stem cells (PBSC) from related non-carrier and carrier donors, BM or PBSCs from unrelated donors, and unrelated partially matched umbilical cord blood units. The Mendelian inheritance of human leukocyte antigen (HLA) and MPS genes restricts the chances of finding a non-carrier matched related BM donor to only about one in 16 of patients [5]. Thus, the majority of patients who may benefit from HCT will need alternate donor sources. In general, there are more published reports of UCBT in the last few years [3,4,19,22,31]. Results of a multinational MPS I registry showed a continuous trend in the proportion of patients receiving stem cells from cord blood or PBSC rather than BM increasing from 26 out of 158 patients (16.5%) before 2003 to 33 out of 65 patients (50.7%) in 2003–2005 and 39 out of 64 patients (60.9%) in 2006–2009 [22]. In various studies, UCBT as the stem cell source in MPS IH patients was associated with higher rates of successful sustained engraftment, compared to bone marrow and peripheral blood (84–85% vs. 26–75%) [14,15,19,23,31]. However, the results obtained using UCBT mainly involved HCTs performed

Table 74.6 Consensus statement prepared by facilitator Ms Jean Mossman on the orthopedic management of mucopolysaccharidosis (MPS) patients who have had a hematopoietic cell transplant (HCT). Consensus position statements arising from conference held October 3–4, 2003 in Manchester, UK

A. General session

Speakers and contributors to this session and their affiliations: Peters, C. currently: The Children's Mercy Hospital, Kansas City, USA, previously: University of Minnesota, Minneapolis, USA; Wynn, R. Royal Manchester Children's Hospital, Manchester, UK; Steward, CG. Bone Marrow Transplant Unit, Royal Hospital for Children, Bristol, UK; Wraith, E. Willink Biochemical Genetics Unity, Royal Manchester Children's Hospital, Manchester, UK; Guffon, N. Centre de Référence des Maladies Héréditaires du Métabolisme, Hôpital Edouard Herriot, Lyon, France.

- As a result of HCT and other emerging treatments for MPS diseases, the management of skeletal abnormalities has become increasingly important
- HCT has favorably altered the natural history of some MPS diseases and can partially correct the skeletal abnormalities
- Multiple lines of accumulating evidence in patients and animals provide compelling evidence that early HCT has a positive impact on skeletal disease, in particular carpal tunnel syndrome and trigger finger
- HCT improves the soft tissue abnormalities associated with MPS diseases
- HCT is expected to be more effective as prophylaxis than treatment
- Skeletal disease varies between types of MPS disease
- The etiology of skeletal disease is uncertain: it is not clear how glycosaminoglycan accumulation leads to the skeletal dysplasia
- At present, it is not possible accurately to predict which children will develop skeletal abnormalities of sufficient severity to require intervention, and ongoing review of the likely orthopedic problems is essential
- The outcome of orthopedic surgery for skeletal and soft tissue problems (genu valgum, hip dislocation, trigger finger, and carpal tunnel syndrome) in the group of patients for whom these symptoms are a problem is encouraging
- Most parents of children who have had surgery have been pleased with the results
- Assessing the long-term outcome of surgical intervention in children who have received bone marrow transplants is important and requires follow-up into adulthood
- An international registry of both treated and untreated patients, including procedures and outcomes, is needed as a matter of urgency
- Data fields collected by registries should have input from patients and families to ensure that the data collected are relevant to the decisions future parents will make regarding treatment for their children

B. Knee surgery session

Speakers and contributors to this session and their affiliations: Ogilvie, JW, currently: Shriners Hospital for Children, Salt Lake City, USA, previously: University of Minnesota, Minneapolis, USA; Meadows, T. Royal Manchester Children's Hospital, Manchester, UK.

- >50% of engrafted patients develop knock knees
- Good correction can be achieved with both stapling and osteotomy
- Changes with growth can result in failure of both procedures, and more than one procedure may be necessary
- Stapling can fail as a result of permanent growth failure of the growth zone on the other side of the knee
- Assessment for knee surgery: in children where there is clinical suspicion of genu valgum, a posteroanterior standing X-ray of the entire lower limbs is indicated

Stapling

- Epiphyseal stapling should be considered when the tibiofemoral angle >~15° *and*
- Epiphysis is ossified enough to hold staple
- Age >4–5 years may be optimal *and*
- There is an expectation of a further 1–2 years of growth remaining
- The staple should be removed when angle is reduced to 0–5°. Two staples, of a design that provides adequate anchorage but which can be removed, should be used

Osteotomy

Osteotomy should be considered when:

- Degree of deformity >~20°
- Stapling has failed to correct the problem
- The deformity is not at the knee
- The patient is too old and therefore there is not enough growing time left
- Acute correction versus graduated correction: Patient preference, in the light of a clear explanation and open discussion of the risks and benefits of both approaches, should contribute to the decision about which approach to use
- Patient groups have an important role to play in producing information setting out the risks and benefits

Osteotomy	Stapling
More morbidity	Less morbidity
Several days in hospital	Outpatient or short stay if not done alongside other procedures
Days or weeks to become ambulatory, depending on procedure	Ambulatory within days

C. Hip surgery session

Speakers and contributors to this session and their affiliations: Meadows, T. Royal Manchester Children's Hospital, Manchester, UK; Ogilvie, JW, currently: Shriners Hospital for Children, Salt Lake City, USA, previously: University of Minnesota, Minneapolis, USA; Garin, C. Hôpital Edouard Herriot, Lyon, France.

- The same basic principles for indication for surgery apply as in non-MPS hip dysplasia:
  - Shallow acetabulum
  - Shenton's line broken
  - Patients for whom longevity is assumed
  - If the degree of dysplasia is likely to lead to
    - early or premature arthritis
    - adverse effect on quality of life is likely

The aim of surgery is to:

- Reduce the hip
- Provide cover
- Early rehabilitation

Hip surgery should be undertaken before the ability to remodel the acetabulum is lost

- Assessment
  - – Anteroposterior X-ray of the pelvis
  - – Consider magnetic resonance imaging

Surgery may be to the pelvis, femur or both

(*Continued*)

Table 74.6 (*Continued*)

The operation technique will depend on:
- Age
- Severity of problem
- Surgical preference

Both hips may be operated on at the same time, depending on the technique used, the general wellbeing of the patient and the preference of the patient/family and the surgeon
One technique which has been used successfully:
1) Single stage
   a) bilateral femoral osteotomy
   b) bilateral iliac osteotomy
      Femoral varus with or without rotation osteotomy
      Degas-type iliac osteotomy
2) 6 weeks in a cast
   a) progressive ambulation
   b) gentle physical therapy

D. Carpal tunnel syndrome session
Speakers and contributors to this session and their affiliations: Van Heest, A and Khanna, G. University of Minnesota, Minneapolis, USA.
- Screening testing for all children with MPS using nerve conduction velocity is essential. Children do not complain of pain, numbness or weakness until the carpal tunnel syndrome is severe and neurologic damage may be permanent. Nerve conduction velocity testing can diagnose carpal tunnel in its milder form, when median nerve compression is reversible
- Nerve conduction velocity with decreased velocity or decreased amplitude or increased latency in median nerve function compared with ulnar nerve function over the same carpal distance is diagnostic of carpal tunnel syndrome
- Untreated carpal tunnel syndrome leads to loss of thenar muscle function and loss of sensation in the thumb, index, long, and part of the ring finger
- Carpal tunnel syndrome in MPS diseases is due to dysplasia of the carpal bones, leading to a narrower bony carpal tunnel, combined with glycosaminoglycan deposits on the flexor tendons within the carpal tunnel, resulting in increased pressure on the median nerve
- Studies have demonstrated that carpal tunnel release surgery improves median nerve function
- With improved blood and marrow transplant techniques, treating patient with MPS IH, approximately 50% of children acquire carpal tunnel syndrome. Decreased risk of developing carpal tunnel syndrome exists for patients transplanted at a younger age and in patients with normal or carrier levels of enzyme post-transplant

E. Trigger finger session
Speakers and contributors to this session and their affiliations: Van Heest, A and Khanna, G. University of Minnesota, Minneapolis, USA.
- Untreated locked trigger finger can lead to permanent hand joint contractures
- Surgical release of the A1 and A3 pulleys with possible resection of half the flexor digitorum superficialis tendon may lead to prevention of contractures if locked digits exist. Stretching exercises for the fingers and night-time splinting do not resolve the underlying cause
- Screening for trigger finger includes palpation of the flexor tendons for nodules as well as documentation of active and passive range of motion of each finger joint

F. Spinal surgery for kyphosis session
Speakers and contributors to this session and their affiliations: Garin, C. Hôpital Edouard Herriot, Lyon, France; Ogilvie, JW, currently: Shriners Hospital for Children, Salt Lake City, USA, previously: University of Minnesota, Minneapolis, USA; Williamson, B. Royal Manchester Children's Hospital, Manchester, UK.
- Purpose of spinal surgery is:
  - to keep the spine balanced
  - to protect neural elements
  - to maximize mobility and function by minimizing the deformity
  - to retain quality of life
- Spinal surgery should only be undertaken after a surgeon with expertise in operating on children with MPS diseases has clinically reviewed the case
- Indications for surgery:
  - these may be different from the indications that would apply to non-MPS children
  - consistent deterioration on serial X-rays
  - clinical need as judged by expert opinion
  - some surgeons operate only when the degree of curvature is in the 60–70° region
- There is a role for patient organizations in educating patients and their families on the need to monitor change in the spine and to be alert to neurologic changes that might arise from spinal changes:
  - Weakness
  - Pain
  - Decreasing activity tolerance
  - Deteriorating bowel or bladder function
- Assessment: standing 2 m posteroanterior and lateral X-ray
- Surgical approach
  - Anterior column support
  - Anterior posterior surgery
- The role of braces
  - There is no evidence that bracing alters the natural history of spinal changes prior to surgery
  - On this basis, if families can tolerate no bracing, it is an acceptable approach to take
- Post-surgical management
  - A cast should be applied in the operating room at the end of surgery and should remain in place for between 6 weeks and 3 months
  - Subsequently, the patient should wear a brace until the bones have healed/united/fused
  - Physiotherapy should only be undertaken with a treatment plan agreed in advance with the surgeon
  - Normal activity can be resumed at 12 months, although this does not include contact sports and other potentially dangerous activities such as tumbling

G. Spinal surgery for scoliosis session
Speakers and contributors to this session and their affiliations: Garin, C. Hôpital Edouard Herriot, Lyon, France; Ogilvie, JW, currently: Shriners Hospital for Children, Salt Lake City, USA, previously: University of Minnesota, Minneapolis, USA; Williamson, B. Royal Manchester Children's Hospital, Manchester, UK.
- Purpose of spinal surgery is:
  - to keep the spine balanced
  - to protect neural elements
  - to maximize mobility
  - to retain quality of life
- Indication for surgery: apply same principles as for non-MPS children
- Spinal surgery for scoliosis should only be undertaken after a surgeon with expertise in operating on children with MPS diseases has clinically reviewed the case

during the last two decades, whereas many of the studies using BM or PBSC have been accomplished over the last several decades. Therefore, these higher rates of successful engraftment in UCB recipients might have been caused by other factors, including changes in conditioning regimen and supportive care. This is supported by a retrospective report by the European Group for Blood and Marrow Transplantation (EBMT) study, analyzing risk factors for graft failure in 146 MPS IH patients [32]. There was no significant difference in engraftment between the use of UCBT, BM, and PBSC stem cells. Although no difference in survival or graft failure could be demonstrated between the recipients of the various stem cell sources, the authors did show that more patients receiving a UCBT achieved full donor chimerism (93%), compared to other stem cell sources (BM and PBSC, 66%: OR 9.31; $p = 0.044$). Furthermore, all patients receiving a UCBT obtained normal enzyme levels, compared to 60% in the other group [32]. Higher incidences of full donor chimerism and normal enzyme levels after UCBT in MPS IH patients was documented by other studies [3,19,31]. This was documented to occur in other forms of inherited errors of metabolism [3,20].

Theoretically, in addition to achieving normal enzyme levels and higher levels of donor engraftment the use of UCB for HCT has several other potential advantages, including:

1. CBUs are readily available, significantly reducing the time between diagnosis and HCT [19,20]. This is particularly important for the rapidly progressive CNS involvement in MPS IH patients.
2. Donors with human leukocyte antigen (HLA) disparities can be used, increasing the possibility of finding a suitable donor [19].
3. Lower rates of acute and chronic graft-versus-host disease (aGVHD, cGVHD) have been reported despite higher levels of HLA incompatibility [3,19].
4. Although highly speculative, there are suggestions of transdifferentiation into cell types such as osteoblasts, chondroblasts, and neurons, because of the more primitive stem cell population in UCB [33].

The theoretical disadvantages of using UCB as a stem cell source are:

1. A protracted duration to engraftment, due to the lower amount of stem cells in UCB.
2. The availability of only one donation per donor.
3. Less adoptive immunity that may increase the likelihood of life-threatening viral reactivations.

These disadvantages are, however, less applicable to MPS IH patients due to their typical young age and small size. These patients require small doses of stem cells in order to obtain successful engraftment and as relatively low graft failure rates are reported after CBT, a single UCB is sufficient in the majority of cases.

In conclusion, UCBT might be the preferential stem cell source for HCT in MPS IH patients as full donor chimerism and higher enzyme levels have been suggested to positively influence the neurocognitive outcome after HCT.

Enzyme replacement therapy and HCT for MPS I

Enzyme replacement therapy is an etiology-specific treatment that seeks to address the underlying pathophysiology of MPS I by delivering sufficient α-L-iduronidase (IDUA laronidase) activity to reverse and prevent GAG accumulation. ERT with recombinant human IDUA, laronidase, has shown efficacy with low toxicity in a randomized, double-blinded, placebo-controlled, multinational phase 3 study [34].

Since the 1980s HCT has proved to be the only known curative measure for the severe form of MPS IH [9]; MPS IS (Scheie syndrome) and MPS IH/S (Hurler-Scheie syndrome), both demonstrating less aggressive phenotypes compared to MPS IH, with normal to mildly delayed neurocognitive development, and survival beyond the first decade and often into the third decade [1]. While HCT can successfully treat MPS IH/S or MPS IS, the significant toxicities associated with HCT and the availability of ERT has made its application in these less severe forms difficult to justify; therefore the use of HCT in MPS IH/S and MPS IS has progressively declined and use of recombinant IDUA increased in treatment of these patients [22,34].

ERT has become a mainstay of therapy for patients with MPS IH/S and MPS IS, the attenuated forms of IDUA deficiency that do not have CNS manifestations. As the intravenous administration of the enzyme has been shown to not effectively cross the blood–brain barrier, the treatment of severe MPS I deficiency with enzyme replacement alone has not been accepted; in the MPS IH (Hurler syndrome) population, HCT remains the standard of care. However, one major consequence of the success of ERT in MPS IH/S and MPS IS has been the potential benefits of adding ERT either prior or after HCT [35,36]. The use of ERT in association with HCT resulted in enhanced cognitive outcomes, providing new evidence that ERT is a valuable addition to standard HCT. Although the mechanism responsible for this improved outcome is unknown, it is possible that both direct and indirect effects may be involved [36].

Outcome of HCT in patients with MPS I

Generally, with successful HCT, children with MPS IH can achieve normal neurodevelopment [19] and do not require ventriculoperitoneal shunting [27]. While age and cardiopulmonary and neurodevelopmental status are important determinants of outcome in patients with MPS IH following HCT, other contributing factors include quality and quantity of developmental services and therapies (e.g., speech and language therapy) as well as the number and severity of specific post-HCT complications such as GVHD, infections, and organ toxicities [14,15,19,23,27,29,37,38]. On occasions when primary or secondary graft failure has occurred, successful long-term engrafted survival with a favorable quality of life has been achieved following a second HCT [39]. Considerable attention has been paid to issues related to quality of life, including musculoskeletal, motor, and adaptive function in Hurler patients after HCT [24,25,40], as well as to optimizing patient safety during and after HCT. ERT using laronidase prior to, during, and after HCT has been administered to reduce the total body burden of GAGs, and theoretically to reduce the likelihood of an MPS-related peritransplant complication [6,7].

Maroteaux-Lamy syndrome (MPS VI)

Epidemiology, molecular biology, and etiology

Mucopolysaccharidosis VI (MPS VI, Maroteaux-Lamy syndrome) is characterized by an absence or deficiency of N-acetylgalactosamine 4-sulfatase (arylsulfatase B) resulting in accumulation of dermatan sulfate. The principal clinical features of children with MPS VI in a survey of 121 untreated patients with MPS VI older than 4 years of age revealed that while MPS VI patients are not known to have primary cognitive impairment due to central nervous system GAG storage, they suffer a broad range of symptoms including short stature, large head with coarse facial features, flat nasal bridge, enlarged tongue, several skeletal and joint abnormalities, valvular heart disease, hernias, weakness, hepatosplenomegaly, airway obstruction, chronic ear and respiratory infections, carpal tunnel syndrome, corneal clouding, poor vision, and blindness [41].

Consequently, patients born with rapidly progressing MPS VI usually suffer severe disability and diminished life expectancy.

Hematopoietic cell transplantation for MPS VI

In the absence of ERT or HCT, life expectancy for rapidly progressing patients is limited to the 2nd or 3rd decades, while slowly progressing patients have a life expectancy into the 5th or 6th decade of life [42]. Following engraftment of HCT, increased arylsulfatase B activity can be demonstrated and there is evidence for overall clinical improvement in the condition of these patients. Long-term improvements in facial dysmorphism, hepatosplenomegaly, joint mobility, and cardiac manifestations has been demonstrated in MPS VI patients following HCT [43]; however, skeletal disease known as dysostosis multiplex tends to persist or progress despite HCT, and visual manifestations show only limited beneficial effects [44].

Prior to the availability of ERT, the clinical management of MPS VI was limited to supportive care and allogeneic HCT; however, due to the rarity of this disease, little is known about the long-term outcomes of HCT for MPS VI.

Outcome of HCT in patients with MPS VI

HCT has been used successfully to treat MPS VI for nearly 25 years [10,43], with resolution of hepatosplenomegaly, airway obstruction, and sleep apnea, prevention of further cardiopulmonary deterioration, and improved joint mobility. Visual acuity improved in some cases [10,43], although corneal haze does not necessarily resolve. As in other MPS disorders, HCT has not treated effectively skeletal abnormalities (Table 74.6). An analysis using aggregate data gathered by the Center for International Blood and Marrow Transplant Research (CIBMTR) between 1982 and 2007 to determine survival probability for patients with MPS VI following allogeneic HCT identified 45 MPS VI patients with a median age of 5 years (range, 1–22 years) at the time they received an allogeneic HSCT. Cumulative incidence (95% CI) of aGVHD at 100 days was 36% (21–53%). Probability of survival was 78% (65–89%) at 100 days and 66% (52–79%) at 1 and 3 years. While these data are based upon small numbers of recipients, they represent the largest series to date and may help clinicians assess the relative risks and benefits of currently available therapies [45].

Enzyme replacement therapy and HCT for MPS VI

A recombinant human arylsulfatase B (rhASB) treatment of MPS type VI is available and has been investigated since 2004. Results of a phase 3 study showed that rhASB was well tolerated and did not result in discontinuation of the study drug or in serious sequelae for any patient. The improvement in functional tests presented for 48 weeks of this phase 3 study confirmed the effectiveness of weekly administration of 1.0 mg/kg rhASB on endurance and urinary GAG excretion and demonstrated a favorable safety profile for this compound in patients with MPS VI. Finally, the improvements in efficacy and safety were confirmed in the follow-on 24-week open-label extension period [46]. With the availability of an effective ERT, the future role of HCT in treatment of patients with MPS VI is unclear (Table 74.6).

Sly syndrome (MPS VII)

Mucopolysaccharidosis type VII (MPS VII; β-glucuronidase deficiency) is a rare autosomal recessive genetic disorder due to an inherited defect in the lysosomal hydrolase, β-glucuronidase, which in turn causes accumulation of undegraded glycosaminoglycans in the lysosomes. The use of HCT for MPS VII is limited by the rarity of the disorder and its predilection toward hydrops fetalis, the neonatal form is one of the few lysosomal storage diseases with clinical manifestations in utero or at birth, although attenuated forms do exist [47]. MPS VII, in certain circumstances, can be ameliorated by HCT provided the neurodevelopmental and clinical status of the patient is satisfactory at the time of HCT [47]. In this case report, the 12-year-old MPS VII patient experienced major improvements in motor and pulmonary function with diminished upper respiratory tract and middle ear infections, leading to an improved quality of life.

Mucolipidoses (ML) types II and III (I-cell disease and pseudo-Hurler polydystrophy)

I-cell disease (ML II) and pseudo-Hurler polydystrophy (ML III) are lysosomal storage diseases caused by abnormal lysosomal enzyme phosphorylation and localization. In both diseases, newly synthesized lysosomal enzymes are secreted into the extracellular medium instead of being targeted correctly to lysosomes. All cells and tissues of affected patients are deficient in UDP-N-acetylglucosamine: lysosomal enzyme N-acetylglucosamine-1-phosphotransferase activity. ML II is characterized by severe psychomotor retardation and shares many clinical and radiologic features with Hurler syndrome. However, clinical differentiation is possible due to earlier onset of signs and symptoms, absence of GAGs in urine, and the more rapidly progressive course, leading to death between 5 and 8 years of age. Neonates with I-cell disease usually show characteristic facial features, craniofacial abnormalities, and restricted joint movement despite generalized hypotonia. Other presenting features may include striking gingival hyperplasia, congenital hip dislocation, fractures, hernias, and bilateral talipes equinovarus. The clinical course includes progressive failure to thrive and developmental delay, usually evident by age 6 months; linear growth decelerates during the first year and stops during the second. Joint immobility progresses, with claw hand deformity and kyphoscoliosis ensuing. Hepatomegaly is prominent while splenomegaly is minimal. Respiratory infections are frequent, as is otitis media. Cardiomegaly and murmurs are common, and aortic insufficiency is not infrequent [21].

Historical experience with HCT for ML II (I-cell disease) existed initially only in patients with end-stage cardiopulmonary disease [48]. Over the past decade, transplant experience with a small cohort of patients ranging in age from 0.3 to 1.7 years has demonstrated that long-term engrafted survival can be achieved in selected patients who continue to make developmental progress, albeit at slower than normal rates [49]. Obstructive sleep apnea may require tracheostomy prior to HCT as well as continuous positive airway pressure or bilevel positive airway pressure support. Further, careful long-term monitoring is required as airway complications and pulmonary hypertension can occur.

MPS DISORDERS FOR WHICH HCT IS NOT BENEFICIAL: MPS II, MPS III, MPS IV

Hunter syndrome (MPS II)

Epidemiology, molecular biology, and etiology

Mucopolysaccharidosis II (MPS II or Hunter syndrome) is a rare genetic disease caused by deficiency of the lysosomal enzyme iduronate-2-sulfatase (IDS). MPS II has an incidence of approximately 0.31 to 0.71 per 100,000 live births and it is found almost exclusively in young males as it is an X-linked condition. Affected females with a clinical picture in many cases similar to that of the young males have been described [50]. MPS II is a chronic, progressive disease with a clinical picture similar in certain aspects to that of MPS I: there is great variability in the clinical manifestations, including CNS involvement, and it can therefore be classified into a severe or "neuropathic" form and an attenuated or "non-neuropathic" form. The more common severe form presents before the age of 3 years with profound neurocognitive and developmental delay, and shares clinical features with MPS IH, including facial dysmorphia, progressive conductive and sensorineural hearing loss, upper airway obstruction with sleep apnea, cardiopulmonary dysfunction, hepatosplenomegaly, joint stiffness, and short stature [51,52]. Dysostosis multiplex is less severe and corneal haze is absent in Hunter syndrome. The attenuated form of MPS II is associated with less neurocognitive impairment and, in some cases, normal intelligence; survival can extend into the fifth and sixth decades, in contrast to MPS IIA (severe Hunter syndrome) with its shortened life expectancy of one to two decades [51,52].

Hematopoietic cell transplantation for MPS II

While HCT seems to help patients with MPS IIA and MPS IIB (attenuated Hunter syndrome) with respect to organomegaly, airway obstruction, and cardiac function, boys with MPS IIA still have demonstrated profound neurocognitive disabilities despite early, successful HCT [26,48,53]. The failure of HCT to favorably alter the long-term neurocognitive outcome in MPS IIA suggests that iduronate-2-sulfatase is not being effectively delivered to essential components of the CNS. In cases of transplanted MPS IIB patients, there have been somatic benefits, and intellectual function has remained intact as expected based upon the natural history of the disorder. Ethical issues continue to arise in the face of limited somatic benefit and minimal-to-absent neurocognitive gains in patients with MPS IIB undergoing HCT [54]. In conclusion, there is little evidence to support the use of HCT in MPS II, Hunter syndrome. To date, only small case series have been reported. These indicate that HCT results in stabilization or improvement in some somatic manifestations of Hunter syndrome, as seen with recombinant ERT, but little or no cognitive benefit has been demonstrated [5,54].

Enzyme replacement therapy and HCT for MPS II

ERT with recombinant human idursulfase (IDS, Elaprase®) has been shown to be a safe and effective therapy across a wide range of ages and disease severity; improving respiratory function, joint mobility, walking ability, and quality of life [55,56]. However, similar to HCT, ERT for Hunter syndrome has not been demonstrated to and is not predicted to cross the blood–brain barrier. Nearly all published experience with ERT with IDS has therefore been in patients without cognitive impairment (attenuated phenotype). Little formal guidance is available on the issues surrounding ERT in cognitively impaired patients with the severe phenotype. The clinical experience of an expert panel convened to provide guidelines based on experience with 66 patients suggests that somatic improvements (e.g., reduction in liver volume, increased mobility, and reduction in frequency of respiratory infections) may occur in most severe patients. Cognitive benefits have not been seen. It was agreed that patients with the severe phenotype are candidates for at least a 6–12-month trial of ERT, excluding patients with a severe neurologic impairment, those in a vegetative state, or those who have a condition that may lead to near-term death. The decision to initiate ERT in severe Hunter syndrome should be made by the physician and parents and must be based on realistic expectations of benefits and risks, with the understanding that ERT may be withdrawn in the absence of demonstrable benefits [57].

Sanfilippo syndrome (MPS III)

Mucopolysaccharidosis III (Sanfilippo syndrome, MPS III) is a lysosomal storage disorder in which there is impaired degradation of heparan sulfate. Though clinically similar, there are four subtypes of MPS III, A–D, each with a unique enzyme deficiency. Neurobehavioral manifestations are the hallmarks of all four types of MPS III [1]. Characteristic findings include extreme hyperactivity, aggressive behaviors, attention deficits, and progressive neurocognitive delay often associated with expressive language disabilities. Unlike other mucopolysaccharidosis, patients with MPS III have early and severe involvement of the CNS with few somatic manifestations. Consequently the typical coarse facial features, organomegaly, and dysostosis multiplex seen in other mucopolysaccharidosis are less prominent in these patients. Cognitive deterioration, however, typically begins between 2 and 6 years of age, and by age 10 years many have profound impairment [1]. As in MPS II, HCT is able to effectively treat the various somatic aspects of MPS III; however, the uniformly poor neurocognitive and developmental outcomes despite fully donor-engrafted marrow transplants performed early in the disease course (Figure 74.4) [58,59] have been attributed to reduced efficiency of uptake of MPS III-specific hydrolases, leading to diminished clearance of substrate. Evidence that the use of umbilical cord blood has a more potent effect on gaining entrance into the brain and being more effective than other sources of donor cells for these and other patients is still

lacking at present. Alternative therapies, including enzyme replacement, are being investigated but are not yet available for any of the MPS type III subtypes. Although clinical efficacy has not yet been fully demonstrated for HCT or any other therapy, it is likely that future developments will lead to disease-modifying treatment for this devastating condition.

Morquio syndrome (MPS IV)

The two distinct biochemical forms of MPS IV have similar clinical features, including severe dysostosis multiplex, dwarfism, atlanto-axial instability, short trunk, and hyperextensible joints with ligamentous laxity. Corneal haze is mild, hepatosplenomegaly moderate, cardiac abnormalities unusual, and intelligence preserved [26]. HCT is incapable of ameliorating the severe skeletal deformities. Therefore, this shortcoming of HCT and the MPS IV clinical features make HCT a suboptimal intervention for this disease.

Leukodystrophies and other white matter diseases

Leukodystrophies are a group of disorders characterized by myelin dysfunction, either at the level of myelin formation or maintenance, resulting either in its impaired development (dysmyelination) or in its destruction (demyelination). In some leukodystrophies, the peripheral nervous system (PNS) may also be affected and the presence of abnormal PNS myelin can be observed. In dysmyelination, myelin formation does not proceed appropriately culminating in myelin with defects in structure and function, which may further increase the susceptibility to myelin damage and loss. On the other hand, demyelination is characterized by a normal synthesis and formation of myelin, which is followed by a decrease or loss of myelin. There are several factors contributing to myelin loss, but as commonly observed in peroxisomal and lysosomal disorders, the accumulation or defect of a given metabolite is generally the major underlying cause. The leukodystrophies are generally rare, but they have a significant impact in the society with an estimated overall incidence of 1 in 7500 live births. Currently, there is no cure for leukodystrophies and the development of effective treatments remains challenging.

In this section, leukodystrophies (X-ALD, GLD, and MLD) will be presented and discussed in detail (see later and Table 74.2); other white matter diseases, such as Alexander disease, Pelizaeus-Merzbacher disease (PMD), vanishing white matter disease (VWMD), and Zellweger syndrome will be presented and discussed in a limited manner (Table 74.2).

X-linked adrenoleukodystrophy (X-ALD)

Epidemiology, molecular biology, and etiology

X-linked adrenoleukodystrophy is a peroxisomal disorder characterized by cerebral demyelination, adrenal insufficiency, and progressive neurologic deterioration. The de novo mutation rate in X-ALD is 7.8% of cases, and in 42% of index cases the first recognized mutation occurs in the mother. The *ALD* gene (located at Xq28) encodes the ALD protein (ALDP, ABCD1), which is a member of the ATP-binding cassette transport protein family (ABC transporters) and is likely involved in transport of fatty acyl coenzyme A substrates or their cofactors into peroxisomes. Its metabolic hallmark is the accumulation of very long chain fatty acids (VLCFA) in tissues and plasma, due to impaired transport and β-oxidation of these fatty acids in peroxisomes. The contribution to cerebral and adrenal dysfunction is poorly understood, significant efforts are directed at achieving a better understanding of the underlying pathophysiology.

X-ALD has a minimum frequency of 1 : 16,800 in the total population and approximately 1 : 20,000 males (Table 74.2) [60]. It predominantly affects males, although 40% or more of female heterozygous carriers exhibit mild-to-moderate non-cerebral signs of the disease. X-ALD is an inflammatory demyelinating disorder that in its most severe form affects children with a rapid and progressive demyelination. The inflammatory demyelination may also affect neurons and their axons [61].

Clinical description

There is no genotype–phenotype correlation in X-ALD; that is, six distinct clinical phenotypes exist independent of VLCFA abnormality or ALDP expression, mutation, or family history. Genotypic analysis definitively identifies the 20% of female heterozygous carriers who can have normal levels of fasting plasma VLCFAs. The clinical phenotypes and their relative percentages are as follows [62]:

- childhood cerebral (30–40%);
- adolescent cerebral (5–10%);
- adult cerebral (~5%);
- adrenomyeloneuropathy (AMN; 40–50%);
- AMN with cerebral involvement (25% of the total AMN cases);
- Addison only (variable percentage, dependent on age).

Childhood-onset cerebral disease, with its median age of onset of 7 years, encompasses adrenal insufficiency in 90% of affected boys.

The predominant pattern of demyelination seen by brain MRI is posterior (i.e., parieto-occipital lobes) in 80–85% of cases. Frontal lobe and pyramidal tract involvement are also seen in 10–15% and approximately 5% of cases, respectively [63–65]. Neurologic deterioration occurs in all boys.

Neurologic deterioration occurs in all boys and can include vision impairment, cortical blindness, hearing, auditory processing problems, aphasia, apraxia, swallowing difficulty, gait and motor difficulties, fine motor deficits, bowel and/or bladder dysfunction, seizures, sparse hair, adrenal insufficiency, and hypogonadism manifested by low testosterone and high luteinizing hormone levels. The MRI of the brain shows characteristic ascending involvement of the pyramidal tracts from the pons to the internal capsules. Of note, men can develop cerebral demyelination that is similar to that seen in childhood cases. Disability, dementia and death can occur within a few months to several years from the onset of clinical symptoms.

A complete evaluation of a boy with cerebral X-ALD includes a thorough neurologic examination; comprehensive neuropsychologic assessment with particular attention to the performance IQ (PIQ), which is a sensitive indicator of deficits in visual perceptual and spatial processing, speed and efficiency of task completion, and novel problem solving; and an MRI of the brain with and without contrast (gadolinium) with an MRI severity score determination, referred to as the Loes score [63].

Boys diagnosed with X-ALD due to a family history merit careful, complete serial monitoring beginning at age 3 years and continuing into adolescence, with the objective being to detect cerebral demyelination at a very early stage and to intervene with HCT in a timely and presumably effective manner. To date, MRI scanning of the brain with gadolinium is the most effective clinical tool to perform serial monitoring. It is strongly recommended that scans be performed at least every 6 months, and more often if there is evidence of the earliest stages of dysmyelination. This is particularly relevant for boys under 10 years of age with X-ALD who have the highest risk for developing childhood-onset cerebral demyelination that is rapidly progressive. However, in no circumstances should HCT be performed in the absence of cerebral disease (see below).

Hematopoietic cell transplantation

The first transplant for childhood cerebral X-ALD was performed in 1982 in a boy with advanced-stage disease; despite a successful graft, he died of progressive X-ALD [84]. However, Aubourg and colleagues in Paris successfully transplanted a boy with early-stage cerebral X-ALD and published their findings in 1990 [14], thus beginning the modern era of successful transplantation for this disorder. HCT is accepted as an effective therapy for the early stages of X-ALD. Shapiro et al. described the long-term results (5–10 years) of transplant in 12 boys [66]. They described the prospects for achieving stability in the extent of MRI demyelination and the changes in neuropsychologic function, with a propensity for deterioration before ultimate stabilization in visual processing as evidenced by PIQ score in boys with a posterior pattern. Interestingly, VLCFA concentrations decreased by 55% but remained elevated in the long term, suggesting that VLCFA levels are not an optimal surrogate marker for this disease. A large, multinational registry of patients with X-ALD showed that only boys with early-stage disease benefit from HCT [17]. The overall 5-year survival was 56% (95% CI, 44–68%). Boys transplanted for early-stage cerebral disease (zero or one neurologic deficit and MRI severity score <9, had a 92% survival at 5 years; Figure 74.5). This report also provided insight into the probability of neurologic deterioration following HCT (Table 74.7). Specifically, in boys with no neurologic deficits before HCT, there was still a 44% likelihood that the neurologic deficit score would increase afterwards [17]. The concept of an ALD-disability rating scale (ALD-DRS) was introduced, although not yet validated (Table 74.8). This scale proved informative in examining neurologic deficits, neuropsychologic function, MRI severity, and ALD-DRS levels after HCT in patients with cerebral X-ALD according to baseline PIQ (Table 74.9). Both PIQ and ALD-DRS levels were significantly poorer after HCT in boys whose baseline PIQ was below 80. The ALD-DRS levels before and after HCT were reported and gave insight into the potential for significant worsening of the level of disability depending on the status of the disease at time of HCT (Table 74.10). Finally, the neuropsychologic functional outcomes of boys after HCT was assessed and reported based upon their MRI pattern of demyelination (Table 74.11). The largest single institution experience of allogeneic HCT for patients with X-ALD [67] showed a 5-year survival of 76% (95% CI, 64–88%). Survival differed based on the severity of cerebral disease, based on Loes score at the time of HCT. For boys with a baseline

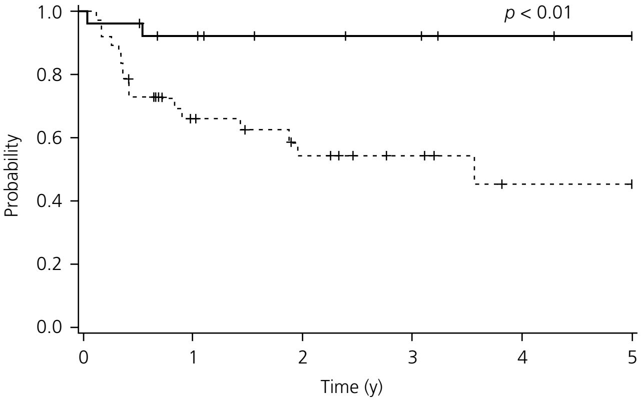

Figure 74.5 Kaplan–Meier estimate of survival for cerebral X-linked adrenoleukodystrophy following hematopoietic cell transplantation by number of neurologic deficits (e.g., limitations of vision, hearing, speech, gait, fine motor skills, and/or activities of daily living) and magnetic resonance imaging (MRI) severity score before transplantation. The solid line indicates patients with zero or one neurologic deficit and an MRI severity score less than 9 ($n = 25$). The dashed line indicates patients with two or more neurologic deficits or an MRI severity score of 9 or greater ($n = 37$). Ticks on the probability lines indicate dates of censoring at last follow-up. y, years. Source: Peters et al. 2004 [17]. Reproduced with permission of the American Society of Hematology.

Loes score <10, survival at 5 years was estimated at 89%, whereas for those with advanced radiographic disease (Loes score ≥ 10), 5-year survival was estimated at only 60% ($p = 0.03$). A trend toward superior survival was seen in boys with no baseline clinical evidence of cerebral disease, Estimate of 5-year survival for this clinically silent group was 91%, whereas that for boys with clinically evident brain disease was 66% ($p = 0.08$). In this study, post-HCT progression of radiographic, as well as clinical neurologic dysfunction, as measured by the functional tests and Loes scores depends significantly on baseline Loes score, functional tests, PIQ, and FSIQ. Data from this study suggest that more extensive cerebral disease at the time of HCT correlates with greater progression of cerebral disease after transplantation. Such neurologic function outcomes data are critical to shaping important decision-making when parents and clinicians are considering HCT for boys with advanced cerebral disease and may prove important in developing alternative therapies for this population [67].

The putative mechanism by which HCT halts the progress of CNS demyelination in cerebral X-ALD is unclear. It has been speculated that immunosuppression contained, together with long-term donor-derived engraftment, would halt the inflammatory process and contribute donor-derived microglia, respectively.

The neurologic benefits of HCT in X-linked adrenoleukodystrophy are mediated by the replacement of brain microglial cells derived from donor bone marrow myeloid cells. To clarify the mechanisms of HCT, intravenous injection was performed in ABCD1 mutant mice [68]. Treatment led to a significant reduction of VLCFA accumulation in the spleen and lung after transplantation, but not in the brain and spinal cord. This correlated with a higher engraftment of transplanted cells in the spleen and lung, along with detection of the ALD protein, and little engraftment in the CNS with no detection of ALD protein [68].

Gene therapy and autologous HCT for X-linked ALD

Adrenoleukodystrophy (ALD) gene transfer with lentiviral vectors in vitro has yielded biochemical correction of monocytes/macrophages derived from ALD protein-deficient human $CD34^+$ cells [9]. The transplantation in vivo of lentivirally transduced murine ALD hematopoietic cells into ALD mice resulted in the replacement of 20–25% of brain microglial cells expressing the ALD protein 12 months after transplantation [10]. On the basis of these promising preclinical data Cartier et al. initiated an HSC gene therapy trial in two X-ALD patients who had developed progressive cerebral demyelination. Both were candidates for allogeneic HCT, but had no HLA-matched donors or cord blood. Autologous $CD34^+$ cells were genetically corrected ex vivo with a lentiviral vector encoding wild-type ABCD1 cDNA, and then reinfused into the patients after a myeloablative conditioning regimen [69]. Over 3 years of follow-up, the hematopoiesis remained polyclonal in the two patients treated with 7–14% of granulocytes, monocytes, and T- and B lymphocytes expressing the lentivirally encoded ALD protein. There was no evidence of clonal dominance or skewing based on the retrieval of lentiviral insertion repertoire in different hematopoietic lineages by deep sequencing. Cerebral demyelination was arrested 14 and 16 months, respectively, in the two treated patients, without further progression up to the last follow-up, a clinical outcome that is comparable to that observed after allogeneic HCT [70]. The results of this study suggest that HSC-based gene therapy is a potential therapeutic option for X-ALD patients with progressive cerebral demyelination as HSC gene therapy abrogates the morbidity and mortality risks associated with conventional allogeneic HCT.

Cell source for HCT in patients with X-ALD

A single-center report of its experience with UCB HCT for 12 patients with X-ALD, including six with early- and very early-stage cerebral disease (Loes scores 3–8) revealed despite HLA mismatching, similar outcomes to those previously reported after HLA-matched bone marrow transplantation [17,59], even when morbidity and mortality is considered [71]. When UCBT was done in children who have not reached the age at which cerebral X-ALD typically progresses, they tolerated the procedure well; continued to have normal neurologic exams, typical development, and no additional changes in MRI scans at 4, 6, and 8 years of age [71].

In the Cord Blood Transplantation (COBLT) study, the median age of the UCB recipient was 1.8 years, and it is unclear if X-ALD patients had evidence of cerebral disease at the time of HCT [3]. In conclusion, the number of patients reported with UCBY is too low to overturn the present recommendation of the National Marrow Donor Program, International Bone Marrow Transplant Registry, and the Working Party on Inborn Errors of the European Group for Blood and Marrow Transplantation for waiting until progressive MRI changes or abnormalities in neurobehavioral testing are evident. The recommendation remains that HCT be reserved for X-ALD patients with early but definite evidence of cerebral disease by brain MRI [72].

Lessons learned and considerations to be given in each case of cerebral X-ALD include

1. the timing of HCT and disease status;
2. the optimal hematopoietic cell source (marrow, peripheral or UCB, HLA match, cell dose, and carrier status of the donor, if applicable);
3. the conditioning regimen: high dose versus reduced intensity;
4. the availability of a multispecialty, multidisciplinary team for evaluation and treatment;
5. quality of life for the patient and his family.

Based upon the long-term outcomes of HCT for cerebral X-ALD, the worldwide HCT experience for this disease, and knowledge of the natural history, the following guidelines can be promulgated: MRI severity score and gadolinium enhancement are highly predictive of the likelihood of disease progression; for example, an MRI severity score of at least 1–3 points or more, and gadolinium enhancement in boys under 10 years of age is associated with approximately 90% likelihood of severe, progressive demyelination [64–66,73]. Boys with advanced disease (i.e., very late stage) manifested by low PIQ (<80), a very sensitive neuropsychologic parameter for visual processing, neurologic deficits, and high Loes severity score [63], typically over 13 points, are poor candidates for HCT. Boys with very early-stage and early-stage cerebral disease defined by Loes severity score between 1 and 8 points who typically are without neurologic and neuropsychologic abnormalities are the best candidates for HCT.

Challenges in use of HCT in patients with X-linked ALD

Despite significant progress in the field of HCT for cerebral X-ALD, a number of limitations and unanswered questions remain:

1. the fact that, in most instances – about two-thirds of cases – HCTs have been performed in symptomatic boys with cerebral X-ALD rather than in boys with early stages of disease who had undergone serial MRI monitoring after receiving the biochemical diagnosis of ALD due to a positive family history of this X-linked disease;
2. our continuing inability to predict phenotype in a boy or an adult man;
3. the need for a measure of cerebral disease velocity;
4. the implementation of a more precise system for staging of cerebral disease prior to HCT that builds upon the following: very early stage = MRI score 1–3; early stage = MRI score 4–8; late stage = MRI score 9–13; very late stage = MRI score greater than 13;
5. the pressing need for newborn screening for X-ALD.

In the meantime, novel approaches to boys and men with very late-stage cerebral disease are also needed. Further, the field of HCT for men with adrenomyeloneuropathy (AMN) and cerebral disease is beginning to be orchestrated on an international front through centers in Germany, The Netherlands, and the United States. Clearly, the need for such cooperation and collaboration is essential, together with international databases and registries with attention to longitudinal outcomes.

Non-transplant approaches

Removal of accumulated VLCFA may, theoretically, be a possible treatment for adrenoleukodystrophy. The primary non-transplantation approach to X-ALD has been treatment with Lorenzo's oil (a mixture of glyceroltrioleate and glyceroltrierucate), which normalizes plasma VLCFA concentrations. There is evidence that, in patients with the biochemical diagnosis of X-ALD who are started on Lorenzo's oil and the special diet, are compliant, and start at an early age, there is a decreased likelihood of developing childhood-onset cerebral demyelination [74]. However, it has no effect in patients with established neurologic deficits, as brain levels of VLCFA are unchanged by the treatment. 4-Phenylbutyrate and fenofibrate are compounds known for their ability to reduce VLCFA levels in cultured cells and in the ABCD1 knockout mice, due to enhanced peroxisomal proliferation and upregulation of genes involved in β-oxidation and fatty acid transport [68]. However, the efficacy and usefulness of these compounds for X-linked adrenoleukodystrophy patients has not been established so far.

Other efforts to improve results related to HCT for cerebral X-ALD have focused on the use of *N*-acetyl-L-cysteine in patients with very late-stage cerebral disease [75], use of advanced imaging techniques such as magnetic resonance spectroscopy to evaluate the brain after HCT [76], and the use of magnetic resonance spectroscopy as well to evaluate for the earliest evidence of changes associated with demyelination [77].

Globoid cell leukodystrophy

Epidemiology, molecular biology, and etiology

Globoid-cell leukodystrophy (GLD) or Krabbe disease is a severe autosomal recessive, lysosomal neurodegenerative disorder caused by deficiency of galactocerebrosidase (GALC) [78]. Although its overall prevalence is 1 : 100,000 births in the general population, the frequency of Krabbe disease is as high as 1 : 150 in certain communities. The resultant accumulation of psychosine, a toxic metabolite derived from galactocerebroside, leads to the death of cells forming the myelin sheath of the nervous system [79,80] (Table 74.2). The condition is characterized by white matter degeneration in the CNS and peripheral nervous system, with large macrophages (globoid cells).

Clinical description

Early infantile Krabbe disease, also known as classic Krabbe disease, presents with sudden onset irritability, startle response to stimuli and developmental arrest between 3 and 6 months of age in a previously healthy infant [80]. Over the course of several months, affected infants develop hypertonicity, seizures, blindness and incapacitation, culminating in death often by age 2 years [80]. Feeding difficulties and aspiration pneumonia are frequent complications. Krabbe disease may present later in infancy, in childhood, or even adulthood. Children with late infantile Krabbe disease present after 6 months of age with symptoms similar to the early infantile form, followed by rapid disease progression and death within 2 years. Juvenile Krabbe disease usually presents acutely with ataxia or spastic paresis between 3 and 8 years of age, followed by a slowly progressive disease course [80]. Intellect, often intact at the onset of symptoms, may deteriorate or remain stable for years to decades after symptoms begin.

Hematopoietic cell transplantation

Treatment for GLD is currently limited to pre-symptomatic hematopoietic HCT [12,20]. The first definitive report on the use of HCT for GLD was published in 1998 and described five cases (four late onset, and one Krabbe disease) [12]. Hematopoietic cell sources included HLA-identical marrow in four cases and UCBT in one. In all cases, high-dose conditioning was administered; total body irradiation was given to one patient. This report provided the proof of principle for the use of HCT in patients with GLD. The four cases of late-onset GLD received their HCT between the ages of 2.6 and 11 years of age, with follow-up from 3 to 9 years. The patient with Krabbe disease underwent HCT at age 2 months, and follow-up of 14 months was reported. The outcomes may be summarized as follows: (1) GALC normalized in all patients; (2) there was normal, stable neuropsychologic function in the three late-onset disease patients; (3) MRI of the brain showed an "improvement in demyelination" based upon reduced abnormal signal intensity; (4) cerebrospinal fluid (CSF) protein normalized in all cases except for the infant with Krabbe disease who still had a CSF protein level of over 150 mg/dL at follow-up, although this was decreased from greater than 550 mg/dL at baseline.

Cell source for HCT in patients with X-ALD

A report of the use of UCBT in patients with classic Krabbe disease included 25 infants, of whom 11 were "asymptomatic" and 14 were symptomatic prior to transplant [20]. Comparison of outcomes between the two groups of patients focused on survival, engraftment/GALC, developmental and neurologic status, and MRI of the brain. The authors found the following: (1) engrafted survival among the asymptomatic infants was seen in all 11 of 11, while it occurred in six of the 14 patients who were symptomatic at HCT; (2) none of the patients achieved normalization of CSF protein; (3) among the symptomatic infants, all had major developmental and neurologic deficits after HCT; (4) significant residua were also present among those transplanted in an asymptomatic condition. Of these 12 patients, only four could be described as functioning normally. Problems included mild-to-moderate expressive language delays and mildly-to-severely impaired gross motor function.

The effect of UCBT on peripheral neuropathy, a significant clinical problem in patients with classic Krabbe disease, was studied in 12 patients with GLD, of whom nine had classic Krabbe disease and three had late-onset disease. Serial nerve conduction studies were performed in patients after HCT, although two did not have pre-HCT studies. Further studies are needed to better assess the clinical significance of the nerve conduction velocity results and how best to express these results; in the case of this report, values were expressed as age-matched standardized ratios [81].

Gene therapy for GLD

Gentner et al. found that forced overexpression of the gene encoding GALC is toxic to both mouse and human stem cells and early progenitors but not to their differentiated progeny. A potentially powerful new therapeutic tool for regulating gene expression is the use of microRNAs, which are small non-coding ribonucleic acids that can either block translation of target messenger RNAs or cause their direct degradation. Gentner et al. showed that a specific microRNA, which is found in hematopoietic stem cells but not in their differentiated progeny, could indeed downregulate GALC expression from a genetically modified construct containing the GALC-encoding gene preceded by a microRNA target sequence. By incorporating miR-126 target sequences into a GALC-expressing vector, they suppressed GALC expression in HSCs while maintaining robust expression in mature hematopoietic cells. This approach protected HSCs from GALC toxicity and allowed successful treatment of a mouse GLD model, providing a rationale to explore HSC-based gene therapy for GLD in humans [82,83].

Advancements in diagnostic and imaging tools

With the promise of pre-symptomatic HCT and the advent of assays to detect lysosomal enzyme deficiencies in newborn dried blood spots, newborn screening programs began to consider the addition of Krabbe disease. New York became the first state to screen for the disorder, using measurement of GALC enzyme activity in dried newborn blood spots, followed by enzyme activity in leukocytes/molecular analysis, when indicated [84,85]. Although diagnosis of the disease in the newborn period can be achieved, significant challenges remain to select patients who will benefit from HCT and to predict post-transplant neurodevelopmental outcome [84]. While further investigation into the long-term outcome of pre-symptomatic HSCT for Krabbe disease is needed, other benefits of newborn screening for the disorder are apparent. These include avoidance of diagnostic delay and the recognition of couples at risk who may benefit from available reproductive options. Recently, the state of Illinois also began screening for Krabbe disease. It is likely that other programs will do so in the future [83,86].

With the development of diffusion-tensor MRI (DTI), there is the promise of more sensitive means to assess myelination patterns. With DTI, the MR signal is sensitized to microscopic movement of water molecules. Water motion in white matter myelination is anisotropic (i.e., has a tendency to diffuse along one direction rather than in all directions), a feature that can be quantitatively and reproducibly measured with anisotropy maps. Another report on patients with GLD described the serial assessment of DTI anisotropy measurements in seven patients with early-onset Krabbe disease who had received UCB HCT. Fractional anisotropy ratios were reported, and all patients exhibited worsening of the white matter signal intensity by conventional MRI [87].

Challenges in use of HCT in patients with GLD

The current limitations of HCT for GLD and remaining unanswered questions relate to the following areas:

1. late-onset GLD cases are very rare, and consequently the experience with HCT is still quite limited;
2. the long-term neurologic, neurocognitive, neurodevelopmental, and quality of life outcomes of patients with classic Krabbe disease who have received UCBT in the first 1–2 months of life;
3. the impact of newborn screening for GLD and whether there is justification for its expansion;
4. international discussion, review, and planning for the future, which is urgently needed.

Non-transplant approaches

Non-transplant approaches to patients with GLD primarily fit under the broad category of supportive care measures and may be directed toward the treatment of seizures, spasticity, feeding difficulties, and constipation.

Metachromatic leukodystrophy

Epidemiology, molecular biology, and etiology

Metachromatic leukodystrophy (MLD) is an autosomal recessive lysosomal storage disorder that is caused by the inherited deficiency of the lysosomal enzyme arylsulfatase A (ASA). ASA catalyzes the desulfation of cerebroside 3-sulfate (sulfatide), an acidic sphingolipid mainly present in myelin sheaths. Deficiency of ASA causes the accumulation and massive intralysosomal deposition of this sphingolipid, which manifests itself as metachromatic staining. Metachromatic leukodystrophy is further characterized by a progressive and widespread loss of myelinating cells leading to severe dysfunction of the nervous system. Neurologic findings may include spasticity, neuropathy, dementia, and seizures. Importantly, the time of onset and severity correlate with residual ASA activity. Of absolutely critical importance is confirmation of the diagnosis by documenting elevation of urinary sulfatides. This is necessary due to the common ARSA pseudodeficiency allele in the general population. MLD caused by saposin B deficiency can present as any form of MLD caused by ARSA deficiency. Multiple sulfatase deficiency associates the signs of MLD with MPS and icthyosis. Saposin B deficiency and multiple sulfatase deficiency share with MLD increased CSF protein, slowed nerve conduction velocities, and increased urinary sulfatides.

Clinical description

The phenotypes of MLD include late-infantile MLD and late-onset forms. Late-infantile (early onset, 0.5–4 years of age) presents generally in the first or second year of life due to loss of motor milestones including gait disturbance, decreased deep tendon reflexes, abnormal speech, loss of neurocognitive skills, optic atrophy, progressive spastic quadriparesis, increased CSF protein, and slowed nerve conduction velocities, culminating in dementia and death within several years. The early juvenile form (late onset, 4–6 years) shows gait and postural abnormalities, emotional and behavioral disturbances, optic atrophy, progressive spastic quadriparesis, increased CSF protein, and slowed nerve conduction velocities. The late juvenile form (late onset, 6–16 years) exhibits behavioral abnormalities, poor school performance, language regression, gait disturbance, slowly progressive tetraparesis, increased CSF protein, and slowed nerve conduction velocities. Finally, the adult form (late onset, >16 years) is characterized by mental regression, psychiatric symptoms, incontinence, slowly progressive spastic tetraparesis, normal or increased CSF protein, and normal or slowed nerve conduction velocities.

Late-onset forms of MLD with disease manifesting during school age, adolescence or adulthood present with progressive motor signs and symptoms, including gait disturbance, clumsiness, tremor, and dysarthria. Gradual decline in neurocognitive function is also observed. Neurocognitive and neurobehavioral symptoms seem to predominate in those patients whose disease first manifests in late teenage years or in early to middle adulthood. In fact, many such cases are misdiagnosed as schizophrenia or major psychosis. New-onset attention deficit hyperactivity disorder in school-age children is typical, and they are often treated for years until mental decline is observed. Attention deficits, impulsive behavior, disinhibition, impulsivity, loss of spatial skills, memory loss, and personality changes, together with features of frontal lobe dysfunction, often progress over years to decades. Peripheral nervous system disease is variably present.

Hematopoietic cell transplantation

The experience with HCT as a therapy for MLD extends over 20 years; however, despite advances in the field, HCT for MLD remains challenging. Results of several reports show that HCT performed in late-onset pre-symptomatic patients could halt disease progression. Nevertheless, HCT is only suitable for patients with mild nervous system involvement and with results only seen in the CNS and not in the PNS [88]. Furthermore, all patients transplanted for symptomatic late-infantile MLD have done poorly in all aspects. Even in the few cases of pre-symptomatic HCT for late-infantile MLD, the results have been disappointing, although cognitive but not motor function has been preserved in some patients. All children who were transplanted prior to the development of symptoms have become wheelchair bound and totally dependent in activities of daily living.

The indolent course in adult cases, and the potential for intervening at an appropriate stage of disease for juvenile-onset cases, permits the potentially effective use of HCT for these forms of MLD. HCT can succeed in stabilizing CNS disease and function while having little to no beneficial effect on the peripheral nervous system [13,59,89,90]. However, results are mixed, in some patients neurologic deficits continue to progress, and HCT may stop major neurologic deficits progression, but not all, only in selected patients [91,92].

Challenges in use of HCT in patients with MLD

The current limitations of HCT for MLD and unanswered questions relate to:

1. the fact that it is virtually impossible to effectively treat (i.e., transplant) cases of late-infantile MLD due to the rapid rate of disease progression;
2. late-onset cases still show significant peripheral nervous system disease after HCT, and the time to achieve CNS stabilization appears to be longer than that observed in patients with cerebral X-ALD or late-onset GLD;
3. the possible role of enzymes (ERT) for the peripheral nervous system in MLD remains unknown or speculative. Important ERT experience with the mouse model of MLD has been published. Results of clinical trials with ERT in children with late-infantile MLD are still pending.

ERT, gene therapy, and cellular therapy for MLD

While ERT therapy has been successful in a number of storage disorders, it has not been efficient for the treatment of disorders with prevailing CNS pathology, mostly, because the blood–brain barrier is considered impermeable to high molecular mass proteins. Apart from this, other significant issues such as immune responses following enzyme administration, persistence of already established degeneration and poor accessibility of specific types of affected tissues, may compromise the ability to restore the enzyme deficiency. In a clinical phase I/II study children with late-infantile MLD were treated with intravenously administered rhASA doses of up to 2.5 mg/kg; no alteration in motor or neurologic dysfunction was ultimately observed. Stroobants et al. have continuously delivered rhASA for 4 weeks in a knockout mouse model, in an effort to bypass the blood–brain barrier, with the use of implanted osmotic pumps in the lateral ventricles of the brain. Their experiment led to a marked improvement of sulfatide clearance and reversal of CNS impairment with the use of a lower dose compared to that administered in intravenous ERT, thus suggesting that intracerebroventricular route of administration might be a promising treatment approach for MLD patients. However, no data regarding this treatment modality in MLD patients is currently available. In summary, ERT represents an important therapeutic regimen for the treatment of systemic and PNS pathology in MLD patients, while the obstacle of delivering the enzyme to the CNS remains a main disadvantage. This problem could probably be solved in the future with the intracerebroventricular or intrathecal enzyme delivery.

Mesenchymal stem cells (MSC) have been shown to induce prevention of loss of nerve conduction velocity. This observation led to a phase I clinical trial in six patients who had previously received matched sibling donor HCTs [93]. They received a single infusion of mesenchymal stem cells (MSCs) ($2–10 \times 10^6$ MSCs/kg of recipient body weight) from the original donor. There was no infusion-related toxicity. It was reported that four patients with MLD had “significant improvements in nerve conduction velocities after MSC infusion” (e.g., peroneal nerve 5–6 m/s and median nerve 8–9 m/s); however, no clinically apparent changes occurred in patients’ overall health or mental and physical development after MSC infusion.

Preclinical studies involving, autologous HCT with gene therapy, intracerebral gene therapy, microcapsulated recombinant cells, oligodendrocytic progenitor cells, neural progenitor cells-neurospheres, and embryonic stem cells, to mention some, are ongoing but not yet ready for the clinical arena [94].

Other white matter disorders

Alexander disease

Alexander disease is a rare, fatal disorder of the CNS that occurs primarily in infants and children. Mutations in the glial fibrillary acidic protein gene have now been shown in a number of biopsy- or autopsy-proven patients with Alexander disease [95]. Histologic demonstration of Rosenthal fibers in brain specimens is no longer required for diagnostic purposes. In infants and young children, Alexander disease causes developmental delay, psychomotor retardation, paraparesis, feeding problems, megalencephaly, seizures, and hydrocephalus. Pseudobulbar and bulbar signs predominate in juvenile cases. Characteristic MRI findings have been reported in Alexander disease. Adult cases, which can be more variable, may resemble multiple sclerosis and include palatal clonus. Although therapeutic options are being investigated, only supportive treatments are currently available [95,96] (Table 74.2).

Pelizaeus-Merzbacher disease

Pelizaeus-Merzbacher disease (PMD) disease is an X-linked disorder caused by various mutations of the X-linked proteolipid protein 1 gene (PLP1) that include copy number changes, point mutations, and insertions or deletions of a few bases. These mutations lead to a clinical spectrum from the most severe connatal PMD, to the least severe spastic paraplegia 2 (SPG2). Signs of PMD include nystagmus, hypotonia, tremors, titubation, ataxia, spasticity, athetotic movements and cognitive impairment; the major findings in SPG2 are leg weakness and spasticity. A diffuse pattern of hypomyelination is seen on MRI of PMD/SPG2 patients. A similar constellation of signs and pattern of hypomyelination lead to the autosomal recessive disease called Pelizaeus-Merzbacher-like disease 1 (PMLD1) and the less-severe spastic paraplegia 44 (SPG44), caused by mutations of the gap junction protein, gamma-2 gene (GJC2), formerly known as the gap junction protein, α-12 gene (GJA12). Magnetic resonance spectroscopy (MRS) and brainstem auditory evoked potentials (BAEP) may assist with differential clinical diagnosis of PMD and PMLD1. Supportive therapy for patients with PMD/SPG2 and PMLD1/SPG44 includes medications for seizures and spasticity; physical therapy, exercise, and orthotics for spasticity management; surgery for contractures and scoliosis; gastrostomy for severe dysphagia; proper wheelchair seating, physical therapy, and orthotics to prevent or ameliorate the effects of scoliosis; special education; and assistive communication devices. There is no rationale for the use of HCT to treat PMD (Table 74.2).

Vanishing white matter disease

Vanishing white matter (VWM) is one of the most prevalent inherited childhood leukoencephalopathies, but this may affect people of all ages, including neonates and adults. Typical cases have their onset in late infancy or early childhood, with neurologic involvement characterized by progressive spasticity and ataxia, seizures, dysarthria, and optic atrophy, in which minor stress conditions, such as fever or mild trauma, provoke major episodes of neurologic deterioration. Brain MRI shows diffuse, symmetric hypomyelination. Typical pathologic findings include increasing white matter rarefaction and cystic degeneration, oligodendrocytosis with highly characteristic foamy oligodendrocytes, meager astrogliosis with dysmorphic astrocytes, and loss of oligodendrocytes by apoptosis. VWM is caused by mutations in any of the genes encoding the five subunits of the eukaryotic translation initiation factor 2B (eIF2B), EIF2B1 through EIF2B5. eIF2B is a ubiquitously expressed protein complex that plays a crucial role in regulating the rate of protein synthesis. VWM mutations reduce the activity of eIF2B and impair its function to couple protein synthesis to the cellular demands in basal conditions and during stress. Reduced eIF2B activity leads to sustained improper activation of the unfolded protein response, resulting in concomitant expression of proliferation, prosurvival, and proapoptotic downstream effectors. Consequently, VWM cells are constitutively predisposed and hyperreactive to stress, in view of the fact that VWM genes are housekeeping genes.

There are no specific treatments for VWMD aside from avoidance of clinical situations recognized to exacerbate the disease, and there is no rationale for the use of HCT to treat VWMD (Table 74.2).

Zellweger syndrome

Zellweger syndrome is a rare autosomal recessive severe peroxisomal disorder affecting infants who demonstrate characteristic facial features, profound hypotonia, seizures, and liver and renal dysfunction. It can be diagnosed on the basis of abnormalities of VLCFAs and plasmalogens (phospholipids in which the group at a C1 of glycerol is an ether-linked alcohol rather than an ester-linked fatty acid). Brain MRI shows polymicrogyria. Treatment focuses on addressing feeding difficulties, various therapies, supportive care measures, management of liver dysfunction (e.g., supplemental vitamin K and fat-soluble vitamins) to control bleeding tendencies; ursodeoxycholic acid, adrenal hormone replacement, and docosahexaenoic acid supplementation. There is no rationale for the use of HCT to treat Zellweger syndrome (Table 74.2).

Glycoprotein metabolic and miscellaneous disorders

In this section, glycoprotein metabolic diseases [fucosidosis, Gaucher disease, α-mannosidosis, and aspartylglucosaminuria (AGU)] will be presented and discussed (see below) (Table 74.3). Miscellaneous disorders [cerebrotendinous xanthomatosis, Fabry disease, Farber lipogranulomatous disease, gangliosidoses (GM1, GM2, and Tay-Sachs and Sandhoff diseases), glycogen storage disease II (Pompe disease), neuronal ceroid lipofuscinosis (CLN1 and CLN2), Niemann-Pick disease, Wolman syndrome, Canavan disease, cystinosis, sialic acid storage disease, sialidosis, multiple sulfatase deficiency, and hypophosphatasia] will be presented and discussed in a limited fashion (Table 74.3).

Fucosidosis

Epidemiology, molecular biology, and etiology

Fucosidosis is an autosomal recessive disorder due to a deficiency of α-L-fucosidase, which results in the accumulation of fucose-containing oligosaccharides, glycolipids, and glycoproteins [97]. Clinical features include progressive cognitive and motor deterioration, seizures, coarse facial features, growth retardation, recurrent infections, angiokeratoma corporis diffusum, visceromegaly, and dysostosis multiplex. Although the disease is panethnic, the majority of patients have been from Italy or the south-western region of the United States. A high frequency of consanguinity has been noted in affected families. A summary of the glycoprotein metabolic diseases (fucosidosis, Gaucher disease, α-mannosidosis, and AGU) is presented in Table 74.3.

Clinical description

The clinical course is variable; the majority of patients have a slow deterioration over several years. In severely affected patients, onset of psychomotor retardation in the first year of life, growth retardation, coarse facies, dysostosis multiplex, and increased sweat chloride [97]. At least two clinical phenotypes have been described, though in actuality there may be a continuum with a wide spectrum of severity. Attenuated phenotypes are characterized by angiokeratoma, longer survival, and more normal levels of sweat sodium chloride. The diagnosis is confirmed by enzyme analysis in leukocytes or fibroblasts, molecular DNA testing, and specific MRI findings [97,98].

Hematopoietic cell transplantation

For fucosidosis, detailed studies of a valid animal model, namely the Springer Spaniel, include the use of HCT after total lymphoid irradiation to correct the enzymatic deficiency [99]. BMT in dogs with fucosidosis is able to increase fucosidase activity in plasma, leukocytes, and visceral tissues [99]. Importantly in the context of a leukodystrophy with a neuronal component, neural tissues also showed increased enzymatic activity. Nevertheless, because the canine model resembles closely the human disease, it has been shown that therapeutic interventions after the appearance of clinical symptoms are ineffective [100,101]. Experience with HCT in fucosidosis patients is limited [102,103]. After successful engraftment, a progressive increase in α-L-fucosidase levels was documented in multiple tissues, including plasma and cerebrospinal fluid. Concomitantly with the increase in enzymatic activity, an improvement in myelination as well as normalization of myelination on MRI examination was observed although there was a decrease in psychomotor functions. The caveat behind the knowledge gathered from the human and canine trials resides in the time of intervention. In disorders like fucosidosis, the rapid decline after the appearance of first symptoms may hinder the benefits of bone marrow transplantation, since the cellular alterations and tissue pathology cannot be rescued by donor-derived monocytes or differentiated cells. Nevertheless, these studies have highlighted the need to improve the diagnosis and functional assessment in this disease to increase the time frame available to consider cellular therapy. Due to disease variability, a definitive conclusion regarding the benefits of HCT cannot be reached at this time.

ERT, gene therapy, and cellular therapy for fucosidosis

A gene therapy trial has been reported in the canine model using retroviral gene transfer into autologous hematopoietic stem cells [104]. Despite the lack of engraftment, given the recent advances in vector design, transduction and in vitro manipulation of bone marrow cells, improved strategies should be pursued to delineate the best approach for defining a cellular therapy for fucosidosis. Kondagari et al. have reported the use of ERT in fucosidosis dogs [105]. Intracisternal delivery of recombinant canine α-L-fucosidase was able to reduce the accumulation of fucosylated glycoconjugates. Given these results and that an ERT can be initiated before the development of symptoms, combinatorial approaches including ERT and transplantation may prove to be more beneficial than a single therapeutic intervention.

Gaucher disease

Epidemiology, molecular biology, and etiology

Gaucher disease is the most common lysosomal storage disorder. It is autosomal recessive and characterized by deficient activity of the lysosomal enzyme glucocerebrosidase and as a result, the accumulation of glucocerebroside in the lysosomes. The glucocerebrosidase gene (GBA) has been mapped to chromosome one, band q21. More than 200 mutations that cause Gaucher disease have been documented. The incidence of Gaucher disease in the general population is less than 1 in 30,000–40,000. It is more prevalent in people of Eastern European (Ashkenazi) Jewish descent with a prevalence of 1 in 1000 and a carrier frequency of 1 in 14 people [106]. The pathophysiologic feature of Gaucher disease is the presence of Gaucher cells derived from the monocyte-macrophage system. Most Gaucher cells are found in the spleen, liver, bone marrow, and lymph nodes causing enlargement and dysfunction of these organs resulting in clinical manifestations.

Clinical description

Classically three types of Gaucher disease have been identified based on the presence or absence of primary CNS involvement and the severity of the disease.

Type 1 Gaucher disease is the most common form accounting for 90–95% of the cases. It is characterized by onset in adulthood and by the absence of primary CNS involvement. However, some individuals, who have severe mutations, present with an onset in early childhood. Type 2 Gaucher disease is characterized by severe neurologic involvement and an onset during infancy. Type 3 Gaucher presents by the onset of neurologic disturbances later in the first decade of life. Types 2 and 3 are very rare and occur in less than 1 in 100,000 of the population. The prototype of type 3 Gaucher disease is found with high frequency in the Norbottnian population of northern Sweden [106].

Typically the infant is normal at birth, with clinical features becoming apparent as the amount of substrate accumulating increases. Bleeding due to thrombocytopenia, anemia, and hepatosplenomegaly are the common early features. Bone involvement is common but is not always associated with symptoms. The symptoms of bone disease when present range from mild pain to severe bone crises. Growth retardation is seen in moderate to severe forms of disease. The neurologic symptoms seen in types 2 and 3 include oculomotor apraxia, opisthotonus, bulbar signs [107]. The clinical course of type 1 Gaucher disease has a broad spectrum of severity ranging from individuals who have been diagnosed in their eighth or ninth decade to children who die of complications during their first or second decade. Most infants with type 2 disease die within the first 2 years of life; and the severity of type 3 is intermediate between types 1 and 2 [108]. A confirmed diagnosis can be made by measuring the glucocerebrosidase activity of peripheral blood leucocytes or cultured skin firm diagnosis can be made by measuring the glucocerebrosidase activity of peripheral blood to establish a disease prognosis [107].

Hematopoietic cell transplantation

Since the pathophysiology of Gaucher disease is due to accumulation of lipid-laden macrophages, HCT was thought of as a logical treatment for the disease. The first successful HCT for Gaucher disease was performed by Ringdén et al. [109]. Multiple reports since that time have documented the feasibility and efficacy of this modality [110–114]. The choice of donor cells has expanded over the last few decades to include marrow from matched or mismatched family members, unrelated donors.

The outcomes of HCT are affected by numerous factors such as donor enzyme level, degree and persistence of donor chimerism, and post-transplant complications [72]. Benefit of transplantation varies between organ systems. Hematologic and physical improvement is rapid and sustained. Reticuloendothelial organs, such as the liver and spleen regress within a few months [72] and there is some evidence that the skeletal changes seen in Gaucher disease regress. The evidence for the beneficial effect of HCT on the regression of the neurologic disease in people with types 2 and 3 is conflicting [109,113,114]. The response is slow and the effectiveness appears to depend on the age of the individual, severity of the disease and its progression at the time of treatment.

ERT, gene therapy and cellular therapy for Gaucher disease

The advent of ERT for Gaucher disease has revolutionized the treatment approach to this disorder. Alglucerase, a human placental β-glucocerebrosidase was modified to expose variable numbers of mannose residues, so that it can be targeted to the macrophages. The Chinese hamster ovary cell-derived recombinant ERT imiglucerase was approved by the Food and Drug Administration (FDA) in 1994 and shortly thereafter replaced alglucerase and became the preferred form of treatment for symptomatic individuals with type 1 disease. Treatment results in significant regression of disease in these individuals and has very few side effects [115]. The main drawbacks of ERT are that weekly infusions of the enzyme are required, and the treatment is very expensive. The estimated annual cost of therapy in the United Kingdom for a 50-kg patient is around £86,000 (around US$110,000) for the medication alone [116]. Furthermore, since the enzyme does not cross the blood–brain barrier, it cannot be effective in types 2 and 3 diseases to improve neurologic symptoms [115]. Improvements in HCT technologies make it a less expensive procedure that offers the potential of permanent cure when compared to ERT. However, the procedure is associated with a mortality ranging from less than 5% to more than 10% depending on the availability of a fully matched donor. Therefore, the standard of care for Gaucher disease remains ERT.

Besides ERT and HCT there are a few new promising treatment options [117]. These include: a newer generation of therapeutic recombinant enzymes (velaglucerase alfa), which improves the delivery of the enzyme to cells and is under development, substrate reduction therapy (SRT), drugs that can cross the blood–brain barrier, pharmacologic chaperone therapy, consisting of specific small molecules that inhibit substrate synthesis, or act as chaperones to increase residual activity of glucocerebrosidase by stabilizing misfolded mutant proteins, preventing endoplasmic-reticulum-associated degradation in proteasomes [117].

α-Mannosidosis

Epidemiology, molecular biology, and etiology

α-Mannosidosis arises from deficient activity of the lysosomal enzyme α-mannosidase [97]. The gene maps to chromosome 19p13.2–q12.

Clinical description

Three clinical types have been suggested [118,119]. Type 1: mild form clinically recognized after 10 years of age, without skeletal abnormalities and very slow progression. Type 2: the attenuated (juvenile–adult, type) phenotype accounts for approximately 10–15% of cases. It is characterized by a slower rate of progression with development of ataxia at age 20–30 and survival into adulthood. Type 3: severe form, immediately recognized, with skeletal abnormalities, and rapidly progressive mental retardation, hepatosplenomegaly, severe dysostosis multiplex, and often death between ages 3 and 12 years.

Hematopoietic cell transplantation

The earliest report of HCT in a patient with α-mannosidosis demonstrated reversal of the somatic changes of the disease, but did not affect lysosomal storage within brain tissue. The conclusion was that HCT may not be a suitable treatment for α-mannosidosis [120]. However, it was noted that the lack of effect could be attributed to the fact that donor cells came from the mother who was a carrier of α-mannosidosis. The hypothesis that early HCT could prevent neurologic deterioration was tested in a cat model. Subsequently, a few reports have shown that intellectual function can be stabilized in selected patients, with improvement in adaptive skills, hearing, and verbal memory function [121].

In summary, the possible benefits of BMT in patients with α-mannosidosis type 3 must be weighed against the overall risk of procedure-related morbidity and mortality. The benefits are greater in younger patients before complications have developed. Therefore, BMT is an option in the first decade of life which makes early identification of affected patients critical.

Aspartylglucosaminuria

Epidemiology, molecular biology, and etiology

Aspartylglucosaminuria (AGU) is an autosomal recessive lysosomal storage disease caused by defective activity of the lysosomal enzyme aspartylglucosaminidase resulting in degradation of Asn-linked glycoproteins. The enzyme is necessary for hydrolysis of the protein–oligosaccharide linkage in Asn-linked glycoprotein substrates undergoing metabolic turnover. Loss of glycosylasparaginase activity leads to accumulation of the linkage unit Asn–GlcNAc in tissue lysosomes. Storage of this fragment affects the pathophysiology of neuronal cells most severely [122]. A specific AGU mutation, representing 98% of the disease mutations, is concentrated in the Finnish population with over 200 patients. The carrier frequency in Finland has been estimated to be in the range of 2.5–3% of the population. So far there are 20 other rare family AGU alleles that have been characterized at the molecular level in the world's population [122].

Clinical description

A growth spurt in infancy is the earliest sign of the disease. Delayed speech development, concentration difficulties, clumsiness and restlessness are common presenting symptoms. Aspartylglucosaminuria is characterized by global developmental delay with onset between 2 and 4 years of age. Delayed speech and motor clumsiness are often preceded by frequent upper respiratory tract infections. Patients reach developmental capacities equivalent to that of a 5- to 6-year-old around puberty and then slowly deteriorate to a severely delayed level by adulthood. Mild connective tissue changes lead to coarse facial features, thickened calvarium, and osteoporosis. Seizures are common later in the disease course, with abnormalities in the differentiation between gray and white matter as well as delayed myelination apparent on brain MRI [123].

Hematopoietic cell transplantation in aspartylglucosaminuria

Only few reports have described the use of HCT in patients with AGU [124–126]. The medical center in Helsinki, Finland, has experience with HCT in three patients with follow-up ranging from 1 to over 5 years including serial MRI and biochemical and clinical examinations [126]. MRIs of the brain in transplanted patients with at least 2 years of follow-up showed nearly normal gray–white matter relationships, and improved neuropsychologic function had also occurred [126]. However, more recently, a longer term follow-up described five AGU patients who had a successful HCT between 1991 and 1997. After long-term follow-up the first two patients were more severely mentally retarded in comparison to non-transplanted patients. In addition, while the general state of health of non-transplant patients was good, the five patients who underwent HCT had post-transplant complications. The authors concluded that HCT cannot be recommended for the treatment of patients with AGU after infancy [124].

Miscellaneous disorders

Cerebrotendinous xanthomatosis

Cerebrotendinous xanthomatosis is a rare autosomal recessive disorder due to defective activity of mitochondrial enzyme sterol 27-hydroxylase (CYP27A) [127]. The gene is found on chromosome 2. More than 300 patients have been reported worldwide and over 50 different mutations in CYP27A identified, most of which result in absences or inactive enzyme. The clinical features include diarrhea, cataracts, tendon xanthomas, and neurologic signs such as dementia, psychiatric disturbances, pyramidal and/or cerebellar issues, and seizures. Strongly suggestive cerebellar findings are noted on brain MRI. Abnormalities of bile acids in urine and serum, and elevated plasma and tissue cholestanol, are the biochemical hallmarks at diagnosis and in subsequent monitoring on treatment with chenodeoxycholic acid. There is no role for HCT in this disorder (Table 74.3).

Fabry disease

Fabry disease is an X-linked recessive inborn error of glycosphingolipid catabolism due to deficient activity of lysosomal hydrolase α-galactosidase A in affected hemizygous males. This defect leads to systemic deposition of glycosphingolipids, predominantly globotriaosylceramide in the following tissues: body fluids, endothelium, perithelium, smooth muscle cells of blood vessels, ganglia, heart, kidneys, eyes, etc. Onset is usually in childhood or adolescence with pain and paresthesias of the extremities, vessel ectasia (angiokeratoma) in skin and mucous membranes, and hypohidrosis. Corneal and lenticular opacities are often noted. With aging, proteinuria, hyposthenuria, and lymphedema appear. Severe renal impairment leads to hypertension and uremia. Causes of death are usually renal, cardiac, or cerebrovascular. Heterozygous females may have an attenuated form of the disease. The gene is located at Xq22.1. Over 150 mutations have been identified, including partial gene rearrangements, splice-junction defects, and point mutations, thereby emphasizing the heterogeneity of the molecular defects causing this disease. The primary treatment is ERT with additional supportive care measures as indicated, such as treatment for neuropathic pain, anticoagulants in patients who are prone to strokes, and hemodialysis for patients with end-stage renal disease. HCT is not considered an appropriate therapy (Table 74.3).

Farber lipogranulomatous disease

Farber disease is a rare lysosomal storage disorder caused by deficiency of acidic ceramidase. Formation of subcutaneous and periarticular ceramide-containing nodules causes painful joint swelling, progressive disability, and hoarseness. The pathophysiology whereby the defect in ceramide metabolism leads to chronic granulomatous inflammation remains to be elucidated. Most patients with Farber disease die of progressive neurologic deterioration early in infancy; however, since there is a wide spectrum of clinical severity/CNS involvement, depending on residual lysosomal ceramide, there is a broad spectrum of disease severity. Children with Farber disease without CNS involvement (Farber disease type 2/3) still have a severe disease due to chronic granulomatous inflammation with progressive joint deformities causing pain and immobility, and effects on the lower airways causing chronic respiratory failure with death before age 20 years. Allogeneic HCT has been attempted in patients with Farber disease based on the reasoning that a population of cells with normal enzyme activity could ameliorate the effects of the deficient enzyme [128,129]. In transplants of two mildly affected Farber patients (type 2/3), granulomatous infiltrations were reduced, the hoarseness disappeared, and joint mobility improved [128]. However, earlier transplants on patients with the more common type 1 Farber disease had limited success. In these studies, BMT lessened the peripheral symptoms but there was no improvement in neurologic function and patients died soon after transplant [129]. In summary, HCT performed in patients with Farber disease and CNS involvement has been unsuccessful, with patients dying of progressive neurodegeneration while peripheral symptoms including granuloma resolved [128].

Gangliosidoses (GM1, GM2, Tay-Sachs, Sandhoff)

The GM2 gangliosidoses are a group of inherited disorders caused by excessive accumulation of ganglioside GM2 and related glycolipids in lysosomes, especially in neurons. With infantile onset, the rapidly progressive neurodegenerative disease leads to death by 4 years of age (classic Tay-Sachs disease, Sandhoff disease, and GM2 activator deficiency), while later onset subacute or chronic forms show more slowly progressive neurologic conditions compatible with survival into late childhood, adolescence, or even adulthood. HCT does not appear to successfully correct these disorders (Table 74.3). Deficiency of lysosomal β-galactosidase is manifested clinically as two different diseases, GM1 gangliosidosis and Morquio B (MPS IVB, discussed previously). GM1 gangliosidosis can have its onset in infancy, childhood/adolescence or adulthood. The clinical course is generally progressive neurologic deterioration. The role of HCT for GM1 gangliosidosis remains unclear since most cases are too advanced at diagnosis or progress too rapidly for benefit to be derived from HCT. Conflicting results have been documented in studies reporting the use of HCT in patients with the various gangliosidoses [130,131]. A few of the reports suggest that HCT may be helpful in later onset cases at an early stage of the disease process.

Glycogen storage disease type II (Pompe disease)

Glycogen storage disease type II is also called acid maltase deficiency or Pompe disease. It is an autosomal recessive disorder of glycogen metabolism arising from deficiency of lysosomal hydrolase acid α-glucosidase activity. The clinical presentation encompasses a range of phenotypes, all of which include varying degrees of myopathy, but differ with respect to onset, extent of organ involvement, and rate of progression to death. Infantile-onset Pompe disease, the most severe form, is characterized by a generalized muscle weakness, hypotonia and a hypertrophic cardiomyopathy with death typically in the first year of life due to cardiorespiratory or respiratory failure. Late-onset forms of Pompe disease (juvenile and adult forms) feature progressive weakness without significant cardiomyopathy. Patients have significant morbidity and with disease progression become wheelchair-dependent and require artificial ventilation. The cause of death in late-onset Pompe disease is usually respiratory failure, which can be precipitous. The histopathology of Pompe disease includes marked lysosomal accumulation of glycogen in cardiac and skeletal muscle, which culminates with the leakage/rupture of lysosomes and cytoplasmic pooling of glycogen. GAA is normally widely expressed from a promoter with resemblance to a "housekeeping" gene [132].

The primary therapies are ERT and supportive care measures. There is not a role for HCT in this disorder (Table 74.3) [132].

Neuronal ceroid lipofuscinosis (NCL1, NCL2)

Two forms of neuronal ceroid lipofuscinosis (NCL1, infantile, and NCL2, classic late-infantile) are recognized as true lysosomal enzyme storage disorders. NCL1 is characterized by normal development until age 6–12 months, followed by psychomotor retardation, microcephaly, myoclonus, and visual deterioration. NCL2 presents between 2 and 4 years of age with severe myoclonic seizures and slow progression to blindness. Since both diseases are lysosomal, the implication is that HCT might be effective therapy [133]. However, this has not been borne out by presymptomatic patients with NCL2 who have been transplanted, or by the existing animal model studies. Additional clinical data are needed to determine whether the natural history of NCL2 is too rapidly progressive for HCT to be beneficial (Table 74.3). Current ongoing trials investigate the therapeutic utilization of cross-correction by enzyme-replacement therapy, gene therapy, and stem cell therapy, which have the potential of translating these treatments into the clinic [133].

Niemann-Pick disease types A, B, and C

Niemann-Pick disease types A and B are lysosomal storage disorders resulting from deficient acid sphingomyelinase enzyme activity. Niemann-Pick type A is a rapidly progressive disorder of infancy characterized by failure to thrive, hepatosplenomegaly, neurodegeneration, and death, often by 2–3 years of age. HCT has not been effective in preventing the inexorable neurodevelopmental decline [134]. Niemann-Pick type B is a phenotypically variable disorder that is usually diagnosed in childhood due to marked hepatosplenomegaly. HCT appears to effectively treat the somatic manifestations of Niemann-Pick type B disease [135].

Niemann-Pick type C is an autosomal recessive lipidosis resulting from a unique error in cellular trafficking of exogenous cholesterol, and is associated with lysosomal accumulation of unesterified cholesterol. A case has been reported of a 3-year-old girl with Niemann-Pick type C disease who underwent allogeneic HLA-identical sibling donor HCT who engrafted. She survived with improvement in somatic disease features including hepatosplenomegaly and marrow and lung infiltration; however, her neurologic status continued to deteriorate [136]. It is therefore unclear whether HCT has a role in the effective treatment of the CNS in Niemann-Pick type C.

Wolman syndrome

Wolman disease is an autosomal recessive disorder of infancy caused by deficiency of the soluble mannose-6-phosphate-targeted lysosomal enzyme acid lipase (AL). Deficiency of this enzyme leads to massive storage of cholesterol and cholesteryl esters. Triglycerides and cholesteryl esters are internalized by the cell through receptor-mediated endocytosis of lipoproteins and metabolized, in part, by AL. The clinical manifestations of this disorder are caused by both accumulation of cholesteryl esters and triglycerides, and toxicity from lipoprotein oxidation. Children affected with Wolman disease develop early hepatosplenomegaly, jaundice, diarrhea, severe vomiting, failure to thrive, and pathognomonic calcification of the adrenal glands. Wolman disease is uniformly lethal in early infancy unless treated with HCT [137,138]. Graft failure and the high mortality rate associated with disease-related pretransplant liver injury and post-transplant liver sinusoidal obstruction syndrome (veno-occlusive disease) have been reported as major barriers to optimal outcomes [137].

Wolman disease is rare and only a few patients underwent HCT. Wolman disease remains near-universally fatal. Curing this disease with HCT is challenging, with the majority of attempts resulting in death because of liver failure from progressive Wolman disease or from other transplant-related complications including infection, GVHD, and failure to engraft. Long-term follow-up data are limited. Tolar et al. report in addition to a lasting correction of hepatic dysfunction, and normal adrenal function that normal neurologic outcome is possible after successful HCT [139]. Their report suggests that timely HCT in patients with Wolman disease, despite management challenges, may potentially be beneficial.

In conclusion, HCT has been performed successfully in a small number of patients and may have a role in a selected group of patients treated prior to onset of permanent organ damage.

Canavan disease

The clinical features of Canavan disease include poor head control and hypotonia at 2–4 months of age, generalized seizures, opisthotonic posturing, loss of very early milestones, increased head circumference, white matter changes (leukodystrophy) on brain MRI, hypotonia that progresses to spasticity, and, late in the course, decerebrate or decorticate posturing [140]. This autosomal recessive disorder arises due to deficient aspartoacylase activity. There is no role for HCT in the treatment of Canavan disease; the primary treatments are supportive in nature (Table 74.3).

Cystinosis

Cystinosis is a rare, autosomal recessive lysosomal storage disorder due to defective carrier-mediated transport of the amino acid cystine across the lysosomal membrane [141]. The major clinical manifestation is renal failure at age 9–10 years. The gene is located on chromosome 17p13 and codes for cystinosin. Therapy includes replacement of renal losses due to Fanconi syndrome, provision of thyroxine, insulin, pancreatic enzymes, and testosterone for deficient patients, and symptomatic care for ophthalmic complaints. Although the potential of hematopoietic stem cell in preservation of kidney function in a mouse model for cystinosis has been investigated, there is no clear role for HCT in cystinosis presently (Table 74.3).

Sialic acid storage diseases

The lysosomal free sialic acid storage diseases, namely Salla disease and infantile free sialic acid storage disease, are autosomal recessive disorders with various degrees of psychomotor retardation. Dysmyelination is an invariable characteristic as seen on brain MRI. The fundamental problem is accumulation of free sialic acid in lysosomes due to an impaired carrier-mediated transport system in the lysosomal membrane. There is no clear indication that HCT is beneficial (Table 74.3).

Sialidosis

Sialidosis is an autosomal recessive disorder consisting of two clinical phenotypes. Type 1, the milder form, is characterized by development of ocular cherry-red spots and generalized myoclonus in the second or third decade, as well as seizures, hyperreflexia, and ataxia. Type 2 disease has an early age of onset, and is a severe and rapidly progressive disorder with an MPS-like phenotype with organomegaly, dysostosis multiplex, and mental retardation [97]. The gene which codes for neuraminidase is found on chromosome 6p21. There is no definitive treatment (Table 74.3).

Multiple sulfatase deficiency

Multiple sulfatase deficiency is a rare (1 : 1.4 million) autosomal recessive disorder characterized by deficiencies in all 12 known sulfatases, and leading to a clinical presentation that generally resembles late-infantile MLD. There has been very limited experience with HCT for this disease, and no definite conclusion can be drawn at this time as to its utility (Table 74.3).

Hypophosphatasia

Hypophosphatasia is an autosomal dominant or autosomal recessive disorder caused by defective osteoblasts and chondrocytes due to inactivation of tissue-non-specific alkaline phosphatase. There is limited experience to date with HCT for this disorder [142].

Future directions

ERT, substrate depletion, alternative stem cells, complementary and combination therapies, gene therapy, alternative approaches to HCT with or without stem cell selection, and newborn screening are all part of this rapidly advancing field of clinical medicine [7,18,143–145]. Alternative and complementary therapies to HCT, as well as combinations of therapies for the inherited metabolic storage diseases, are either in place or being developed. ERT has been available for patients with Gaucher disease type 1 for over 15 years [117]. ERT has made the transition from clinical trial to proven therapy for Fabry, Pompe, and Niemann-Pick type B diseases, and selected MPSs including MPS I, II, and VI. In the case of Fabry disease, ERT reduced severe neuropathic pain, stabilized renal function, and improved cardiac and vascular structure and function. In Pompe disease, a fatal cardiac and skeletal muscle disorder due to acid maltase deficiency, ERT has improved cardiac function and structure and increased overall muscle strength. Important lessons from these experiences include the variability of the clinical response to ERT depending upon the disease, the organ or tissue, the dose of enzyme, and the schedule of administration. Of particular importance is the observation that there is limited-to-no penetration by exogenous intravenous enzyme into the CNS or peripheral nervous system. In the area of substrate depletion or deprivation, a number of disorders have been treated, including Gaucher disease, GM2, Fabry disease, and cystinosis. Drugs that slow the rate of formation of accumulating glycolipids are under development as well.

Alternative stem cells, including both embryonic and adult stem cells, are being investigated in transplantation and gene transfer/therapy trials. This is important since bone marrow-derived MSCs remain host derived despite successful HCT with engraftment in patients with lysosomal and peroxisomal disorders.

The scope of gene transfer applications in therapy for human diseases continues to expand and includes genetic storage diseases. Hematopoietic stem cells have been considered appropriate targets for therapeutic gene transfer due to their ability to self-renew as well as differentiate into multiple lineages. Diseases such as Gaucher disease, Hurler syndrome, X-ALD, MLD, and other enzyme-deficiency states may be amenable to treatment by gene transfer into hematopoietic stem cells, due to enzyme production, release, and uptake leading to metabolic correction. In conclusion, enhanced interactions among the many disciplines and specialists caring for patients with these complex disorders are of paramount importance to the coordinated advancement of this very exciting field of clinical medicine and research.

CHAPTER 75

Hematopoietic Cell Transplantation for Macrophage, Granulocyte and Osteoclast Disorders

Rajni Agarwal
Division of Stem Cell Transplantation and Regenerative Medicine, Department of Pediatrics, Stanford University School of Medicine, Stanford, CA, USA

Introduction

The human body is equipped with a complex phagocytic and immune system to defend against a wide variety of microbes ranging from viruses to bacterial and fungal offenders. The first line of defense is a set of two systems, namely, the monocyte–phagocyte system and the granulocyte–phagocyte system. The primary cells of these two systems, monocytes and granulocytes, arise from a common committed progenitor in the bone marrow [1–3]. The pattern of the inflammatory response in the monocyte–phagocyte system is similar to that seen in the granulocyte–phagocyte system. Any quantitative or qualitative defect in the elements of these defense systems will result in an inadequate host defense against microbial infections.

The monocyte–phagocyte system is defined as a continuum from monoblasts to promonocytes to monocytes with eventual migration of the monocytes into tissues such as lungs, liver, spleen, and the brain to form fixed tissue macrophages that perform specialized functions suited for the specific location. The life span of monocytes varies between 3 and 6 days. The tissue macrophage does not usually undergo cell division and their life span is estimated to range from weeks to years. However, if the cell proliferation regulatory controls are lost or altered, uncontrolled proliferation and accumulation of macrophages may take place in multiple organs. One such example is the hemophagocytic lymphohistiocytosis (HLH) as described later in this chapter. In HLH (familial or secondary), excessive accumulation of tissue macrophages results in organ dysfunction/enlargement. The excessive "cell eating" behavior of the macrophages seen in HLH results in low blood counts. Abnormal proliferation and accumulation of macrophages at specific anatomic sites may result in signs and symptoms pertinent to those sites. For example, central nervous system (CNS) involvement may result in serious clinical focal neurologic manifestations including hypotonia or hypertonia, convulsions, hemiplegia/tetraplegia, or blindness.

The functions of the monocyte–macrophage system are manifold [3]. The mononuclear phagocytes play an important role as phagocytic and immunoregulatory cells. As phagocytic cells, macrophages secrete a variety of antimicrobial agents including lysozyme, neutral proteases, acid hydrolases, and cytokines. The macrophages, for example, secrete the cytokine interleukin-1 (IL-1). Interleukin-1, in turn, stimulates vigorous production of hydrogen peroxide and toxic oxygen metabolites not only by the macrophages but also by the neutrophils. The activation of macrophages in response to insults such as infection is central to their role in host defense. Intact chemotactic mechanisms result in the accumulation of macrophages at the site of insult. Defective mononuclear phagocytic chemotaxis may result in an inadequate host defense against infection such as seen in mucocutaneous candidiasis. The immuno-regulatory functions of the macrophages are also diverse and complex. Macrophages process and present antigens to lymphocytes and secrete cytokines important for the development of lymphocytes and the regulation of their replication. The immune responses are mediated via secretory products that have pleotropic effects affecting nearly all cell types. Macrophages also participate in removing immune complexes from the circulation.

The inflammatory cascade of the granulocyte–phagocyte system has two major components: (1) vasodilatation and increased vascular permeability to phagocyte products, and (2) leukocytic events. The leukocytic events include several sequential steps, some of them overlapping in nature: (1) margination, (2) adhesion to the endothelial surface, (3) emigration which includes "rolling and diapedesis," (4) phagocytosis and intracellular degranulation and killing, and (5) release of leukocyte products. The leukocytic events are elucidated in detail in Figure 75.1.

Initially, pro-inflammatory cytokines such as TNFα, IL-1, IL-6, and IFNγ are released by endothelium, T and B cells resulting in vasodilatation and increased vascular permeability. Immunoglobulins and the complement system activate phagocytes and enhance microbial opsonization. A redundancy of chemoattractants, such as various cytokines and complement fragments, are generated to ensure that the leukocytes will be attracted to the site of insult. The chemoattractant molecules also upregulate certain adhesion receptors on the leukocytes as well as promote recruitment of the cytoskeletal actin for movement of phagocytes.

Following margination or peripheral orientation of leukocytes in the moving blood stream, the white cells adhere in great numbers to the endothelial surface and eventually migrate to the infected or the injured site. The initial step in the emigration of white cells, often referred to as "rolling" or "tethering," is mediated by a family of glycoprotein adhesion molecules called selectins (L-, E-, and P-selectins). Some of the rolling leukocytes become firmly attached to the vascular endothelium via β integrin adhesion receptors on the leukocytes. The integrins are the glycosylated heterodimers of non-covalently linked β and α chains. The type of β integrin is determined by the type of the β subunit in the complete molecule. An important type of β integrin is the β_2 integrin. Three

Figure 75.1 The acute inflammatory response. Neutrophils are among the first cells to arrive at the scene of an infection and are important contributors to the acute inflammatory response. As the neutrophil rolls along the blood-vessel wall, the L-selectin on its surface binds to carbohydrate structures such as sialyl-LewisX on the adhesion molecules on the vascular endothelium, and its progress is eventually halted. As the neutrophil becomes activated, it replaces L-selectin with other cell-surface adhesion molecules, such as integrins. These molecules bind E-selectin, which is present on the blood-vessel wall as a result of the influence of inflammatory mediators such as bacterial lipopolysaccharides and the cytokines interleukin-1 and TNFα. The activated neutrophil then enters the tissues, where it is attracted to the infection site by a number of chemoattractants. The neutrophil can then phagocytose and destroy the C3b-coated bacteria. (For a color version of this figure, please see the color plate section.)

different β_2 integrin molecules result when the same β_2 integrin subunit (CD18) is linked with different α subunits (CD11a, CD11b, and CD11c). Defective adhesion has been noted in an inherited heterogeneous defect called leukocyte adhesion deficiency type I (LAD-I). In this disorder, mutations in the common β_2 integrin subunit are the underlying cause of defective chemotaxis. Two patients have been described with the absence of neutrophil receptors for E-selectin resulting in defective adhesion, and the disorder is called LAD type II.

The emigration of the adhered or firmly attached leukocytes at the endothelial surfaces into the site of injury or infection involves the presence of a chemotactic gradient that creates the directional movement, the chemotaxis, of the cells. The phagocytes move by extending pseudopodia the interior of which consists of a branching network of actin filaments and the contractile protein, myosin. Defects in neutrophil motility involving actin have been noted in neutrophil actin deficiency syndromes. In the next step, the accumulated leukocytes recognize the opsonized targets by attaching to the latter via opsonin receptors on leukocyte surfaces. The major humoral opsonins that coat the microbes include IgM, IgG1, IgG3, C3b, and C3bi. In LAD-I, ingestion of C3bi-opsonized microbes is also impaired. Once the leukocyte–opsonin interaction has occurred, the process of engulfment is initiated.

As the final step, the engulfed material is destroyed through intracellular cytocidal and digestive activity. This process involves oxygen-independent (in the hypoxic necrotic environment of tissue injury) and the oxygen-dependent pathways of microbial killing. In the oxygen-independent pathway, numerous cationic antimicrobial proteins contained within the neutrophil azurophilic granules are utilized. These antimicrobial proteins include proteins such as defensins and serpocidins. In addition, the azurophilic and specific granules also contain other degradation enzymes such as lysozymes and hydrolases. Deficiencies in neutrophil granule proteins or defects in granule formation or degranulation are associated with recurrent bacterial infections as seen in Chediak–Higashi syndrome (CHS). The oxygen-dependent pathway of intracellular microbial killing, often referred to as “respiratory burst oxidase” or NADPH pathway, utilizes the generation of superoxide radicals through mitochondrial-based reactions. Mutations in the oxidase subunit result in the well-known disease entity of chronic granulomatous disease (CGD).

In addition to the normally functioning granulocytes, adequate numbers of granulocytes are necessary for normal host defense. Granulocytopenia due to congenital defects, malignancy, or after administration of chemotherapeutic agents results in increased susceptibility for bacterial infections.

The congenital disorders that affect the monocyte–macrophage and granulocyte system present in early childhood with recurrent, severe and often life-threatening infections. This chapter will address the various disorders of macrophages and granulocytes and the role of hematopoietic cell transplantation (HCT) as an important treatment modality (Table 75.1).

Table 75.1 Hematopoietic cell transplantation for macrophage and granulocyte disorders

Macrophage disorders
Hemophagocytic lymphohistiocytosis
Granulocyte disorders
Quantitative disorders
Kostmann syndrome
Reticular dysgenesis
Cyclic neutropenia
Cartilage-hair dysplasia
Dyskeratosis congenita
Shwachman-Diamond syndrome
Qualitative disorders
Neutrophil actin deficiency – Abnormal chemotaxis
Leukocyte adhesion (CD11/18) deficiency – Abnormal adhesion
Chediak–Higashi syndrome – Abnormal granulation
Chronic granulomatous disease – Abnormal oxidation
Griscelli syndrome

General considerations for HCT

Timing of HCT

The timing of intervention in the phagocytic disorders with HCT depends on the nature of the disease, presence of serious infections, and the status of organ function. Even though the risk attendant to HCT may be a concern, a "wait-and-see" approach may not be in the patient's best interest. Timing of HCT should be determined by the prognosis and the anticipated risk of life-threatening infections or irreversible organ damage. The disorders with a variable clinical course need to be approached differently as opposed to disorders where delayed intervention with HCT might result in high mortality despite the provision of optimal supportive care. For example, in cyclic neutropenia, low counts can be managed with granulocyte colony-stimulating factor (G-CSF) and without intervention with HCT. On the other hand, in severe forms of reticular dysgenesis (RD), early intervention with HCT is warranted [4]. The course of chronic granulomatous disease (CGD) can be extremely variable. However, certain phenotypes of CGD can be more severe than others [5].

Choice of donor for HCT

Since the disorders discussed in this chapter affect young children, genotypically identical donors will likely be available for no more than 20–30% of patients. Therefore, 70–80% of HCT candidates are without an ideally matched related donor for HCT. Since many of these disorders occur in children of consanguineous parents, an extensive family search should be conducted to identify a suitable related donor. The siblings or any other related potential donor should be tested, if technically possible, for the presence of the disease in question before they are considered to serve as donors. Many congenital disorders of the phagocyte system are transmitted as autosomal recessive conditions. The carrier state does not result in serious clinical disease and heterozygous individuals may qualify as donors. One possible exception would be the X-linked CGD, where severely imbalanced "lyonization" may result in clinically significant disease [6]. For HCT in HLH preference should be given to the sibling donor. However, the sibling donor should be screened to rule out the presence of any occult disease. If all the available tests including low NK-cell activity are negative, the sibling may be used as a donor. The caveat that should be kept in mind is that no definitive tests exist to exclude the carrier state. In the event that the sibling is suspected to be a possible carrier, a search for a matched unrelated donor should be performed [7]. Identification of such a donor may require several months and HCT risks may rise during the search process. In general, T-cell-depleted haplo-identical grafts from parents have been successfully used as matched unrelated donors to perform HCT in these patients. However, the difficulties and risks with these HCT procedures remain a major concern.

Preparative regimens

Most of the HCT procedures for phagocytic disorders have been performed utilizing myeloablative conditioning. The two major chemotherapeutic agents in use are busulphan (BU) and cyclophosphamide (CY). Cyclophosphamide is used, under certain circumstances, in combination with total body irradiation (TBI). It remains the physician's choice to use a particular regimen, as both radiation-based and non-radiation-based regimens are relatively well tolerated by children. Since the introduction of hyperfractionated TBI, many of the previously observed long-term effects have diminished. Recent experiences suggest that lower doses of TBI may result in prolonged mixed and eventual complete chimerism, which may be effective and less toxic in HCT procedures for some disorders [8]. More data need to be generated to prove the usefulness of this approach for children with the conditions discussed in this chapter. At this time, reduced-intensity conditioning (RIC) regimens seem to be attractive and should be explored. The RIC approach can be especially useful where mixed chimerism could restore the cellular function, for example in patients with CGD.

Macrophage disorders

Hemophagocytic lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) is the most frequent disorder of the macrophage system. HLH is characterized by multisystem inflammation, a reactive process resulting from the hyperactivation of antigen-presenting cells (macrophages, histiocytes) and CD8+ T cells. In this disorder, accumulation of activated macrophages along with hemophagocytosis of the hematopoietic cellular elements takes place resulting in organ enlargement with dysfunction and cytopenias. The pathologic findings in HLH arise from persistently elevated levels of proinflammatory cytokines. It is now believed that increased exposure to the cytokines generated by uncontrolled activation of histiocytes and T cells leads to progressive organ dysfunction that leads to death in affected patients. Ongoing hypercytokinemia results from failure of natural immune downregulation due to defective NK and cytotoxic T-lymphocyte function [9].

Several genetic defects have been described in HLH. The first genetic defect causing HLH was reported in 1999 involving Perforin gene mutation (PRF1) [10]. Perforin is stored in the NK, CD8+ T and NK-T cells, and is required to deliver granzyme B to target cells that initiate apoptotic programs leading to cell death [11]. The perforin gene mutation is shown to be involved in 20–40% of all affected families, and up to 50% of North American families [12]. In 2003, another gene mutation in UNC 13D on chromosome 17q25 was shown to lead to HLH [13]. The affected protein, Munc 13-4, is essential for cytolytic granule secretion preceding vesicle membrane fusion. The mutated Munc protein results in defective cytolytic granule exocytosis. A third gene defect associated with HLH has recently been identified encoding a protein Syntaxin 11. This involves the gene *STX11* on chromosome 6q24. The Syntaxin 11 has been postulated to play a role in intracellular trafficking [14]. Mutations in the UNC 13D and STX11 affect 20% and 10% of HLH patients, respectively [15]. From a diagnostic standpoint, a rapid screening assay for PRF mutations by flow cytometry has been developed. Genetic sequencing of PRF and MUNC 13-4 genes is also available on a clinical basis in the United States [16].

Hemophagocytic lymphohistiocytosis (HLH) includes two different conditions: (1) primary or familial HLH, an autosomal recessive disorder, and (2) secondary HLH which includes an infection-associated hemophagocytic syndrome and a malignancy-associated hemophagocytic syndrome. Since HCT procedures have been performed only for autosomally recessive primary HLH, we will discuss this entity here.

Primary HLH has been reported from all continents and all ethnic groups. In a retrospective study the incidence of the disease in Swedish children was estimated to be 0.12 per 100,000 children per year [17]. Since primary HLH is an autosomal recessive disorder, an increased incidence has been reported in families with consanguinity [18]. Most patients develop the disease in early life with about 70% of children presenting in the first year of life. However, the age of presentation may be up to 8 years. The age of onset is usually similar among the multiple affected siblings. However, on occasion, a difference of more than 1 to 3 years in age has been noted in affected siblings.

The diagnosis of HLH may be difficult. Diagnostic guidelines have been developed based on clinical, laboratory and histopathologic criteria by the Histiocyte Society in protocol 2004 [12,19]. In the absence of family history or genetic diagnosis, five or more of the eight diagnostic criteria need to be met for the diagnosis of HLH. The guidelines encompass clinical, laboratory and histopathologic findings in the disease (Table 75.2).

The clinical manifestations may vary widely. Although serious central nervous system (CNS) involvement may occur in the disease, the most common early findings include fever, hepatomegaly, and splenomegaly.

The laboratory findings include cytopenias, hypertriglyceridemia, elevated ferritin, and hypofibrinogenemia. Markedly reduced or absent natural killer (NK) cell and T-cell activity have been found to be associated with primary HLH [20]. The association between NK activity and HLH is of great interest due to its potential diagnostic value. It has been found that almost all children with verified familial disease have extremely low or absent NK-cell activity and this value only normalizes after successful HCT. By contrast, those patients with secondary HLH who have low NK-cell activity at presentation normalize their NK-cell activity as the primary condition resolves. The differentiation of familial HLH from secondary HLH may be difficult as about half of the patients present with infections and the family history at the time of presentation may or may not be helpful. In this situation, testing of the NK-cell activity and its normalization pattern may be helpful in distinguishing the primary and the secondary disease. This observation makes it mandatory to test for the NK-cell activity prior to the initiation of HCT.

Table 75.2 Revised diagnostic guidelines for HLH

The diagnosis of HLH can be established if either (A) or (B) below is fulfilled.

A. A molecular diagnosis consistent with HLH: pathologic mutations of PRF1, UNC13d, Munc18-2, Rab27a, STX11, SH2DIA, or BIRC4

OR

B. Diagnostic criteria for HLH fulfilled (five out of the eight criteria below)
Initial diagnostic criteria (to be evaluated in all patients with HLH)
1. Fever
2. Splenomegaly
3. Cytopenias (affecting >2 of 3 lineages in the peripheral blood:
   Hemoglobin <9 g/dL (in infants <4 weeks: hemoglobin <100 g/L)
   Platelets <100 × 10^9/L
   Neutrophils <1.0 × 10^9/L
4. Hypertriglyceridemia and or hypofibrinogenemia:
   Fasting triglycerides >3.0 mmol/L (i.e., >265 mg/dL) and/or
   Fibrinogen <150 mg/dL
5. Hemophagocytosis in bone marrow or spleen or lymph nodes
   No evidence of malignancy
6. Low or absent NK-cell activity
7. Ferritin >500 μg/L
8. Elevated soluble CD25 (i.e., alpha chain of soluble IL-2 receptor) >2400 U/mL

The histopathologic criteria of diagnosis include infiltration of the bone marrow, lymph nodes, liver and spleen with non-malignant lymphocytes and histiocytes, in addition to the evidence for hemophagocytosis in these tissues [21].

HCT procedures have been performed only for autosomally recessive primary HLH. If not treated, the primary HLH is rapidly fatal with a median survival of about 2 months [22]. Several treatment strategies with cytotoxic agents have been tried in the past without much success. The most effective of these moderately effective strategies was the combination of Vinblastine and steroids. The treatment of HLH has also included etoposide (VP-16) in combination with other agents [23]. Approximately 60% of patients have also received CNS treatment with intrathecal methotrexate and cranial irradiation [18].

Immunosuppressive drugs such as cyclosporine (CSP) and antithymocyte globulin (ATG) have been shown to be effective in HLH [24] for short-term control of disease. Historically, the probability of survival at 5 years had been found to be 10% with all patients ultimately succumbing to their disease. In 1994, the Histiocyte Society developed a treatment protocol (HLH-94) designed for treatment of primary HLH [25]. The protocol includes initial treatment with CSP, VP-16, and steroids with consideration for HCT when patients attain remission.

Fischer et al. achieved the first major breakthrough in the treatment of this fatal disease. An allogeneic HCT procedure was performed successfully, which had cured the disease in the patient [26]. Since then, several reports have been published describing the efficacy of HCT using related or unrelated donors. Most of the reports have originated from single HCT centers or from transplant registries [27–30]. The current consensus indicates that HCT should be performed after an initial 8 weeks of treatment with chemotherapy if a suitable donor is available. Patients without a suitable donor should continue to receive standard dose chemotherapy. It is preferred that the patient should be in a stable or quiescent disease state before an HCT procedure is contemplated.

In a follow-up study to the first publication of results with HLH-94, it is clear that the HCT procedure for primary HLH offers an excellent chance of cure. On the HLH-94 protocol, the estimated overall 3-year probability of survival after HCT for patients recruited during the period of 1995–2000 was 64%. The specific survival between different types of grafts used, however, varied. The 3-year survival was 71% with matched related donors, 70% with matched unrelated donors, 50% with family haplo-identical donors and 54% with mismatched unrelated donors [31] . However, the results indicate that the long-term disease-free outcome was comparable for unrelated donor transplants and matched sibling donors (approximately 70% at 3 years). In contrast, the use of T-cell-depleted grafts from haplo-identical donors has met with less success (50% survival at 3 years). A study by Chardin et al. has published the largest cohort of 48 patients with HLH undergoing HCT [32]. The major determinant for the failure and death in the transplanted patients was found to be active disease at the time of HCT. In fact the combination of active disease with T-cell-depleted haplo-identical graft resulted in the worst outcome (Figure 75.2). It may be possible that the active disease hampered donor cell engraftment because of a possible inhibitory effect of cytokines on hematopoiesis. As suggested by this and other reports, it is of great importance to perform HCT as soon as complete remission has been obtained for the disease [16,32].

HLA-matched sibling donors are the preferred choice for HCT in this disorder. However, one caveat that should be kept in mind while selecting a sibling donor is that an apparently healthy sibling donor may develop HLH later. If this occurs, then it is possible that the disease will be transferred from the donor to the recipient. As mentioned earlier, presence of extremely low or no NK-cell activity could be used as a guide to select the sibling donor for HCT in primary HLH. With the mutation analysis available as a diagnostic tool it is essential that the prospective sibling donor be checked for specific mutations. In the event that a suitable sibling donor is not available, alternative donors should be sought. Alternative donor options include: unrelated donors of marrow or human umbilical cord blood and closely matched relatives.

The preparative regimens in most of the published cases have consisted of chemotherapy, containing myeloablative doses of chemotherapeutic drugs. Most of the centers have used high-dose BU, CY, and VP-16 as the conditioning regimen [30]. In some patients, additional immunosuppression has been provided by ATG or the anti LFA-1 monoclonal antibody. These regimens have been well tolerated by children with HLH. Total body irradiation has not been favored as histiocytes may not be sensitive to this measure.

During the past decade RIC regimens have become more available and results have been very promising [33,34]. The idea behind these regimens comes from the fact that mixed chimerisms are able to sustain patients with HLH in remission. Most of these regimens have included alemtuzamab and are demonstrating better post-transplant outcomes. A single-center experience has been published using direct comparison of myeloablative to the reduced-intensity regimen demonstrating the superiority of reduced-intensity protocols [35].

Following HCT, patients usually achieve full donor chimerism. However, repeated analyses should be performed at regular intervals. In some cases, a mixed chimeric state can persist with low quantities of donor cells present in the graft. It is known that mixed chimerism >10–20% is associated with stable complete remission for up to 20 years [16,32]. Secondary graft rejections have been seen below the threshold level of 10% donor cells in the chimera. In patients with declining levels of donor cells, follow-up studies are important as a progressive decrease in donor cells may indicate early relapse and the need for further intervention.

Overall, the major causes of death following HCT for HLH are transplant-related complications including graft failure, infections, and graft-versus-host disease (GVHD). In a few cases, progression of the CNS disease has occurred within weeks after HCT. Active or

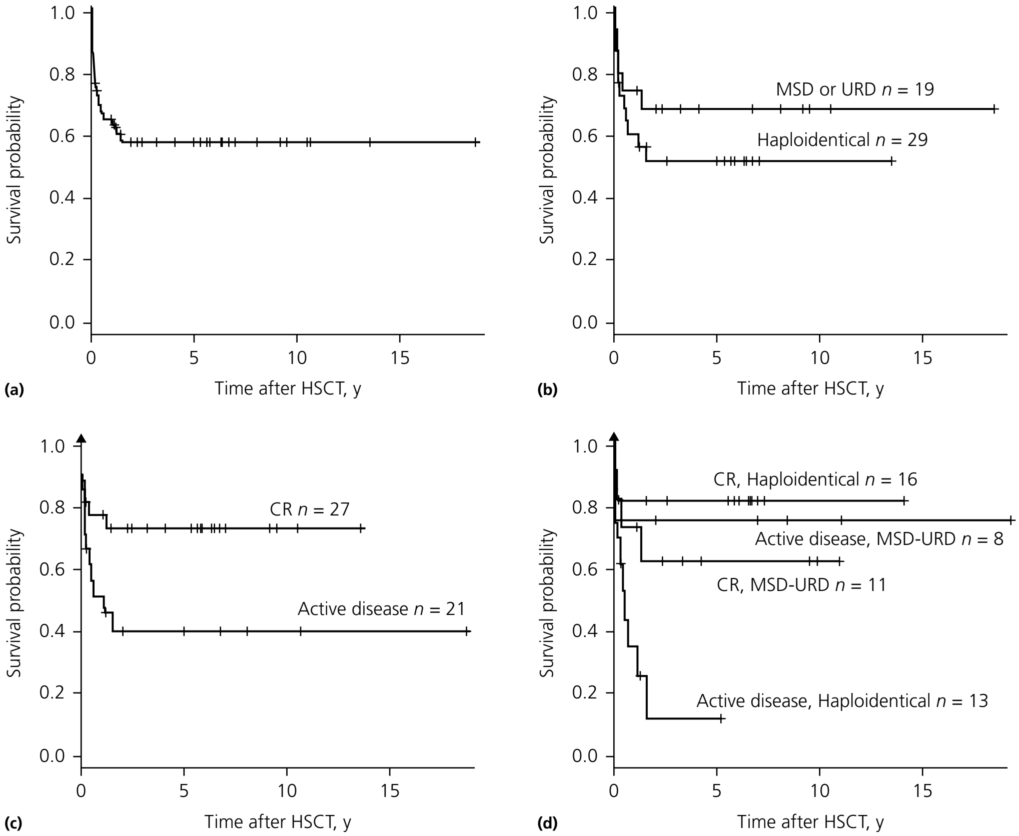

Figure 75.2 Survival of patients with HLH after HSCT. (a) Overall survival (n = 48) calculated from the time of the first attempts at HSCT. (b) Survival according to donor origin. Because of low numbers and similar data, patients who received a transplant with an MSD and a URD have been grouped together (p = 0.3 log-rank test). (c) Survival related to status of HLH at HSCT (CR vs. AD; p = 0.053 log-rank test). (d) Survival according to a combination of donor compatibility and disease activity (for patients with AD, MSD-URD vs. haplo-identical HSCT, p = 0.03 log-rank test; for patients in CR, p = 0.39 log-rank test). AD, advanced disease; HSCT, hematopoietic stem cell transplant; MSD, matched sibling donor; URD, unrelated donor. Source: Ouachee-Chardin et al. 2006 [32]. poorly controlled CNS disease before HCT initiation has led to deterioration after transplantation. The relapse rates for the underlying disease have been reported in the range of 0–55% [28–30]. Actuarial 5-year disease-free survival (DFS) in HLH patients who underwent HCT has been compared with those HLH patients who did not receive the HCT procedure. This DFS was reported to be 66% in HLH patients who were transplanted versus only 10% in those patients who did not receive HCT (Figure 75.3).

Most long-term survivors of HCT for HLH experience a good quality of life, and are able to discontinue all disease-related medications. Stabilization and improvement of neurologic symptoms is commonly seen. Volume loss of the cerebrum and demyelination often seen during the height of HLH disease activity is reversible within 1–3 years of successful engraftment. Long-term follow-up of survivors of BMT for HLH indicates that most children return to a normal quality of life. However, children who have severe neurologic problems in the beginning due to HLH may have persistent cognitive problems and learning disabilities. For this reason, neuropsychiatric evaluation is recommended before the transplant and on periodic basis at regular intervals post-HCT.

HLH is rare in adults and mostly presents as secondary HLH. It is difficult to diagnose secondary HLH on the basis of clinical symptoms alone as the presenting symptoms are usually of the primary disease. Therefore, it seems that secondary HLH is a heterogeneous disease. Since hemophagocytosis is the hallmark of this disease a retrospective analysis was performed in adults with features of secondary HLH who had demonstrable hemophagocytosis in the bone marrow [36]. Most patients were older than age 40 and had associated EBV infection. Genetic mutations were not known in these patients. Patients were treated as per HLH protocols. Mortality was high and patients did not greatly benefit from the HCT in this study. We feel that secondary HLH in adults seems to be a heterogeneous disease with poor understanding of the genetic basis and therefore the appropriate treatment options have not been possible so far.

In summary, there have been major strides in the understanding of HLH at the molecular level. HLH protocol 2004 includes changes reflective of increased understanding in the diagnosis and treatment of HLH .The use of HCT in this disease has provided the best results and remains the treatment of choice as chemotherapy alone is not curative. Adequate therapy to achieve remission before HCT should be attempted since the transplant outcome appears to be improved when patients are in remission.

Granulocyte disorders

The granulocyte disorders are discussed here as the *quantitative* disorders where the number of granulocytes are low or as *qualitative* disorders where the function of granulocytes is altered. Both groups of disorders are very heterogeneous and vary widely in their clinical severity.

Quantitative granulocyte disorders

Neutropenia is defined as a condition where circulating neutrophils are less than 500/μl. Severe neutropenia means an absolute neutrophil count of less than 200/μl. Severe neutropenia is often associated with life-threatening infections, especially if it is prolonged or is associated with immune deficiency. Neutropenia is common to a heterogeneous group of disorders resulting from decreased production or release of maturing and differentiating myeloid precursor cells from the bone marrow. Neutropenia may be primary congenital or secondary acquired. This part of the chapter will cover the intrinsic maturation and differentiation defects of the early myeloid precursors.

Severe congenital neutropenia (Kostmann syndrome)

Severe congenital neutropenia (SCN), also known as Kostmann syndrome (KS), is an inherited disorder with an undefined inheritance pattern. It occurs with an estimated frequency of about 1–2 cases per million with equal gender distribution. A persistent absolute neutrophil count (ANC) of 0.2×10^9/L or less is required for making a diagnosis. Recurrent bacterial infections usually occur in the first year of life. Typically, these patients experience in early infancy recurrent pneumonia, otitis media, gingivitis, and perineal or urinary tract infections. Until recently, 50% of these patients died as a result of infections before 1 year of age, and only 30% had survived beyond 5 years of age [37].

The biology of SCN is not completely understood. At the cellular level, a maturation arrest of myelopoiesis at the promyelocyte or myelocyte stage occurs resulting in neutropenia [38]. Contrary to the earlier suggestions of defective G-CSF production or defective response of the cells to G-CSF, the current data indicate normal or even increased endogenous G-CSF biological profile and activity in cells of patients with SCN. In vitro measurements of colony-forming units – granulocyte macrophage (CFU-GM) also appear to be normal.

G-CSF receptor mutations at birth have not been noted in the SCN patients. These mutations have, however, appeared in those SCN patients who had developed leukemia or MDS later in their lives [39]. This observation suggests that these G-CSF receptor mutations are acquired and may not have a causal relationship with the genesis of this disease. The identification of mutations within the *ELA2* (Elastase-2) gene as a cause of cyclic neutropenia has led to similar studies in patients with SCN. Heterozygous *ELA2* mutations have been found in 60% of the patients with SCN [40]. Analysis of SCN families with autosomal dominant inheritance of elastase mutation and a case with mosaic expression of mutant *ELA2* has provided the strongest evidence to implicate *ELA2* mutations in the etiology of SCN. In addition to *ELA2* mutations, a number of genetic aberrations have been found in patients with disorders associated with KS. Genes that have been found to be mutated in a minor subgroup of patients are *GF1*, *CXCR4*, *SBDS*, *WASP*, Glucose-6-phosphatase translocase, Taz-1, *AP3B1*, and some others [41].

It is now well established that patients with SCN are at risk for development of myelodysplastic syndrome (MDS) and acute myeloid leukemia (AML). The acquisition of G-CSF mutations in SCN patients can be used advantageously to predict the risk of subsequent development of leukemia/MDS in these patients. In a recent report from the SCN International Registry (SCINR), 375 patients with SCN were followed for the development of MDS or AML. The potential risk for the development of MDS/AML increased with the duration of SCN. The cumulative incidence of MDS/AML was 9% after 6 years of therapy. The incidence increased to 23% after 10 years and 33% after 12 years [42–44]. These ominous findings have been linked to point mutations in the G-CSF receptor gene [45,46]. Cytogenetic abnormalities such as monosomy 7 have also been noted in these patients. In light of these findings, SCN can be considered a preleukemic condition.

Based on clinical response to G-CSF treatment, SCN patients have been categorized into G-CSF responders and G-CSF non-responders. This conclusion was initially deduced from data on 304 patients enrolled on SCINR in 1994 [47]. In this study, 95% of the patients had responded to G-CSF treatment. The G-CSF responders have been treated with G-CSF therapy in doses of 3–10 μg per kilogram per day. This response was biologically explained on the basis of normal or increased expression of G-CSF receptors on the cells. Since the myeloid precursor progenitors in SCN patients retain the capacity to differentiate to normal myeloid cells in response to pharmacologic doses of G-CSF [47], a continuous treatment strategy with recombinant G-CSF has been adopted for most of the SCN patients. The continuous treatment with G-CSF results in an increase in the number of mature myeloid cells in the circulation and a concomitant decrease in the incidence of serious infections.

Those patients who do not respond to G-CSF doses of 120 μg/kg/day, and still suffer from bacterial infections, are classified as the G-CSF non-responders or patients refractory to this treatment. This population constitutes about 5% of the patients in the SCINR study group mentioned earlier. In the non-responders, the G-CSF gene defect has not been elucidated. The G-CSF non-responders and those patients who develop cytogenetic and G-CSF receptor mutations during the course of the disease are considered candidates for HCT. All SCN patients who develop MDS/AML are also considered candidates for HCT. The monitoring for cytogenetic and G-CSF receptor mutations is, therefore, emphasized for two reasons: first, for timely intervention with HCT, and secondly, for prediction of risk for developing MDS/AML in these patients with subsequent HCT procedure.

A limited number of patients with SCN, including those documented in the IBMTR registry, have undergone HCT procedures using HLA-identical sibling donors. One patient received CY as a single preparative agent, and attained only partial lymphoid engraftment for 6 months [48]. Another patient received an HLA-identical sibling donor transplant at 20 months of age. This patient is reported to be alive and disease-free 20 years after the HCT procedure [49].

In 2001, a successful fully matched unrelated donor transplant procedure was performed in a G-CSF non-responder [50]. The preparatory regimen contained TBI, VP-16, and CY. Anti-thymocyte globulin was administered to prevent graft rejection. The patient engrafted promptly and the pre-existing pulmonary abscesses resolved. In 2004, Goyal et al. reported successful engraftment following unrelated donor transplantation in an alloimmunized patient with SCN [51]. At our own institution, we have successfully transplanted a G-CSF non-responder with unrelated donor graft using a high dose conditioning regimen (unpublished data). This patient is 5 years post-HCT with full donor chimerism. The conditioning for matched unrelated donor transplants has been fully myeloablative with either busulfan (BU), cyclophosphamide (CY) and ATG, or total body irradiation, BU and ATG. With advances in supportive care, fully matched unrelated donor transplants have an excellent chance of success in patients with SCN. Reduced-intensity conditioning regimens are currently being developed for consideration in patients with high risk of toxicity [52].

To summarize, HCT remains the only curative therapy for SCN. The indications for HCT are in high-risk patients who fail to respond to G-CSF in doses more than 8 μg/kg/day, development of MDS or AML, and patients who have the Gly 185 Arg mutation in the *ELANE* gene [53]. As suggested by Choi and Levine, patients who do not meet these criteria should also be considered for transplant if an available matched sibling is identified, given their continued risk of death from sepsis and leukemia [54]. Alternative donor transplants are becoming more common in non-malignant conditions as improvements in donor selection, GVHD prevention and supportive care make HCT a safer option. Pre-transplant chemotherapy in SCN patients with MDS/AML has an important bearing on the outcome of HCT in these patients. In a report by Choi et al., a cohort of six patients has been reported who developed MDS/AML while on therapy with G-CSF. All six patients received HCT. Four of these six patients who died because of transplant-related complications had frank AML, and had received pre-transplant chemotherapy. Two patients who survived had early MDS and had not received any chemotherapy before the transplant. These findings emphasize the importance of frequent monitoring of all SCN patients for prompt recognition of the development of clonal chromosomal abnormalities and MDS for early intervention with HCT in these patients [43].

Reticular dysgenesis

Reticular dysgenesis (RD) is a rare congenital disorder characterized by severe combined immunodeficiency and agranulocytosis manifesting with life-threatening fulminant infections. The term reticular dysgenesis was introduced in 1959 when two male twins were reported with this syndrome who subsequently died of the disease [55]. An autopsy was performed on these patients and the findings showed depletion of lymphocytes and Hassall's corpuscles in the thymus, absent lymph nodes, tonsils or Peyer's patches, and lack of myeloid activity in the bone marrow [55]. At the molecular level, the primary defect in RD has not yet been identified. At the cellular level, a maturation arrest in the myeloid lineage beyond the promyelocyte stage has been observed along with global impairment of lymphoid maturation. However, erythropoiesis and megakaryopoiesis are found to be normal in RD indicating the existence of an intact pluripotent hematopoietic stem cell pool in these patients. These observations are utilized to make a diagnosis of RD using established clinical and laboratory data namely agranulocytosis, lymphocytopenia, bone marrow finding of early myeloid maturation arrest, failure of in vitro assays to produce mature granulocytes from precursors, lack of lymphocyte functions, and thymic aplasia. In contrast to other variants of severe combined immune deficiency with neutropenia, in RD no sustained responses to myeloid growth factors have been observed. So far, the only curative treatment described for RD is allogeneic HCT.

Untreated patients with RD die from infections within the first days or weeks of life. Prior to 1983, nine cases with this disorder were reported. Their survival ranged from 3 days to 17 weeks [56–60]. In 1983, a cure was reported for reticular dysgenesis following an HCT procedure from an HLA-identical sibling [60].

A preparative regimen of BU and CY was used and the patient achieved full hematopoietic and lymphoid reconstitution. Several other reports have since been published on successful HCT in RD patients using HLA-identical, T-cell-depleted, HLA-haplo-identical, and umbilical cord blood unrelated donor grafts [27,60–67]. In one report using unrelated umbilical cord grafts the patient failed to engraft initially but fully engrafted after a second unrelated cord blood transplantation procedure [66].

A challenging feature of HCT for reticular dysgenesis is not only the choice of the donor but also the intensity of the conditioning treatment to obtain both lymphoid and myeloid reconstitution. This observation has been repeatedly substantiated from data on HLA-haplo-identical transplants. A T-cell-depleted haplo-identical graft had been successfully transplanted following administration of BU, CY and ATG [58]. In one report, using haplo-identical donors, two patients could be re-transplanted successfully only when an intensive high dose conditioning regimen consisting of 700 cGy of TBI was utilized prior to the HCT procedure [64]. In another report, 10 patients receiving HLA-haplo-identical grafts were studied where half of them were given intensive BU/CY conditioning while the other half received either low-dose BU with CY or ATG with CY without BU [67]. Three of the five patients who had received intensive high dose conditioning survived with lymphoid and myeloid reconstitution. The group that did not receive the intensive preparatory regimen or was treated with regimen without BU failed to demonstrate stable engraftment of donor hematopoietic stem cells. This finding, again, indicates the paramount importance of using intensive conditioning prior to the HCT procedure in RD patients.

Cyclic neutropenia

Cyclic neutropenia is usually a familial disorder in which patients have regular cyclic fluctuations in the number of blood neutrophils. The genetic transmission may be autosomal dominant with variable expression [68]. The gene responsible for cyclic neutropenia has been identified as *ELA2* [69]. Clinical signs and symptoms include fever, malaise, periodontitis, mucosal ulcers, sore throat, and lymphadenopathy. Most patients live normal life spans with gradual amelioration of symptoms. Ten percent of patients experience frequent serious infections. The laboratory investigation reveals periods of severe neutropenia (<200 neutrophils/μL) lasting for 3–10 days alternating with periods of normal neutrophil counts. The cyclic fluctuation occurs usually every 21 days with a range of 14–36 days. For each individual patient the cycle length is constant. Bone marrow precursors also reveal concomitant cyclic oscillations. Bone marrow myeloid precursor cells are present in highest numbers at the time of nadir of peripheral neutropenia. Therapy with G-CSF improves the neutrophil counts and reduces the frequency of symptoms.

Clinical manifestations of cyclic neutropenia do not justify the use of HCT. However, HCT has contributed towards a better understanding of this disorder. In an autosomal recessive collie dog model cyclic neutropenia can be corrected by HCT [70]. To date, no human transplants have been reported for cyclic neutropenia. In one patient who was transplanted with an allogeneic donor graft with cyclic neutropenia, the disease was found to be transferred to the recipient during an HCT procedure [71].

Cartilage-hair hypoplasia

Cartilage-hair hypoplasia, an autosomal recessive disorder, is encountered primarily in the Amish and Finnish populations. The abnormal gene for cartilage-hair hypoplasia is located on the short arm of chromosome 9 [72]. Characteristic findings include short-limbed dwarfism, fine hair, moderate to severe neutropenia (ANC 100–200/μL) and defects of cell-mediated immunity [73,74]. The combination of neutropenia and cellular immunity defects lead to recurrent bacterial and viral infections especially reactivation of the varicella zoster infection in these patients. Allogeneic HCT has been used to correct the hematologic and immunologic defects of cartilage-hair hypoplasia [75,76]. Expectedly, the phenotypic hair and bony abnormalities have not been corrected by HCT. Six patients with cartilage-hair hypoplasia have been reported to have undergone HCT. One of the six patients received the preparative regimen consisting of CY, cytosine arabinoside, and thioguanine. This patient achieved complete lymphoid engraftment of donor origin and demonstrated otherwise mixed chimeric hematopoiesis. The remaining five patients received BU and CY and achieved full donor chimerism for lymphoid as well as all other hematologic parameters. The experience with allogeneic HCT is still limited; however, severely affected patients seem to benefit from the procedure.

Dyskeratosis congenita

Dyskeratosis congenita (DC), a rare congenital syndrome, was originally described in 1906. DC is genetically heterogeneous, and all three patterns of inheritance have been recognized [77]. However, the majority of the patients are males and the defective gene has been linked to chromosome Xq28. This genetic defect results in a defective nucleolar protein called dyskarin which is associated with human telomerase RNA (hTR) [77]. In dyskeratosis congenita, like Fanconi anemia, associated DNA repair defects have been noted. Clinically, DC is a multisystem disorder marked by nail dystrophy, oral leukoplakia, increased skin pigmentation, and variable degree of bone marrow aplasia. Bone marrow failure is the principal cause of death followed by predisposition to malignancy and pulmonary failure. Immunologic manifestations include defective cell-mediated immunity [78,79].

Allogeneic bone marrow transplantation has been used successfully to correct the hematologic abnormalities [80]. It is noted that patients with this syndrome require less intensive conditioning [80]. Twenty-two patients have been reported in the literature to have undergone HCT with high dose conditioning. Of the 22 patients, only four patients received grafts from unrelated donors. Ten of the patients survived longer than 3 years post-transplant. In addition to developing short-term complications like organ damage and sepsis, long-term complications carried a high mortality rate [80]. Veno-occlusive disease, pulmonary fibrosis, and renal microangiopathy developed months after HCT. In a published report of five patients with DC-associated severe aplastic anemia who had received HCT using HLA-identical related donor grafts, four patients died 2–8 years post-HCT with renal microangiopathy, veno-occlusive disease of the liver, Evans syndrome, or invasive aspergillosis [81]. One living patient at the time of publication had developed anemia, polyarthritis, pulmonary fibrosis, and gastrointestinal malabsorption syndrome 7.5 years after the HCT procedure. In view of the occurrence of the late HCT-associated complications, it is important that a complete baseline evaluation of kidneys, liver, and respiratory tract be performed prior to the initiation of the HCT procedure in these patients.

Since patients with DC have shown poor tolerance to high dose conditioning regimens, reports using RIC approaches have emerged [82,83]. In one report using RIC, the patient received 200 cGY of TBI and 90 mg/m^2 of fludarabine in a matched sibling donor setting.

GVHD prophylaxis was with mycophenolate mofetil and cyclosporine. This patient achieved 100% donor chimerism with excellent clinical outcome 2 years post-transplant [82]. In another report, two children with DC underwent unrelated donor transplant with RIC with fludarabine, CY and ATG. The prophylaxis for GVHD was provided with steroids and cyclosporine. Both of the patients did very well with full donor chimerism [83].

There have been several reports in the past 3 years that encouraging short-term survival can be achieved with HCT in patients with DC using reduced-intensity regimens [84–86]. Whether long-term toxicity is also reduced with low-intensity conditioning regimens remains to be seen in longer follow-up. However, the use of certain conditioning agents such as busulphan and irradiation should be avoided because of the increased predisposition of the DC patients to chromosomal instability, tumorigenecity, and pulmonary and vascular complications.

Umbilical cord blood has also been used as a donor choice in patients with DC with good engraftment [87].

Shwachman-Bodian-Diamond syndrome

Shwachman-Bodian-Diamond syndrome (SBDS) is an autosomal recessive disorder characterized by exocrine pancreatic insufficiency, metaphyseal dysostosis, and bone marrow hypoplasia [37]. Cyclic or persistent neutropenia is a common finding. However, in 10–25% of patients trilineage pancytopenia may also be seen. Recurrent bacterial infections occur early in childhood and can contribute to early mortality. Progression to myelodysplasia and transformation to acute leukemia are seen in patients who have pancytopenia as the predominant finding. Overall survival without any treatment varies with different subpopulations. In patients without hypoplasia and leukemic transformation, the projected 50% survival is 35 years. However, this expectation is reduced to 24 years in patients with pancytopenia and further decreased to 10 years in those with leukemic transformation [37].

Approximately 90% of patients meeting clinical criteria for the diagnosis for SBDS carry mutations in the *SBDS* gene. *SBDS* maps to the 7q11 centromeric region of chromosome 7 [88]. *SBDS* is a highly conserved gene of unknown function. In humans the SBDS protein is localized to both the cytoplasm and nucleus, and shuttles in and out of the nucleolus in a cell cycle-dependent manner.

Conceivably, HCT would be the only curative treatment option for the bone marrow dysfunction in SBDS [89]. However, mixed results have been observed with allogeneic HCT as a therapeutic approach for SBDS patients with hematologic abnormalities. Fifty-eight patients have undergone HCT for bone marrow failure and or leukemic transformation with SBDS. Most of the published data comes from case reports and small series of cases [90–92]. Patients have received grafts from matched sibling donors, matched unrelated donors, and human umbilical cord blood. The conditioning regimens were either with BU/CY/ATG or TBI/CY. Forty percent of the transplant patients died due to HCT-related complications of sepsis, regimen-related toxicity, and GVHD. Risk of graft failure did not appear to be significantly elevated. As expected, the patients with marrow aplasia had a relatively better survival than the patients with MDS or leukemic transformation. A single report exists for the use of RIC in a patient with SBDS/AML who received an unrelated donor transplant. Full engraftment is reported in this surviving patient [90]. At the moment follow-up of these patients is relatively short. Long-term studies will be needed to look at the real impact of HCT in SBDS patients.

Qualitative neutrophil disorders

The major role of neutrophils is to defend the host against a variety of infectious agents. To accomplish this task the neutrophils must first sense infection, migrate to the site of infection (chemotaxis), adhere to the membranes of the blood vessel wall and then destroy the offender (phagocytosis) through the release of granules that take part in the activation of oxidative dependent and oxygen-independent pathways of microbial killing. The presences of these different components of the microbial killing cascade are essential for the appropriate function of neutrophils. In the qualitative disorders discussed later, neutrophilia is usually present in response to infection. However, one or more of the functional components of the neutrophil attack may be faulty.

Neutrophil actin abnormality

This is a rare inherited autosomal recessive disorder in which defective granulocyte motility leads to inadequate chemotaxis resulting in serious recurrent infections. Granulocyte counts are, however, either normal or even elevated. This disorder was initially described in an infant in 1974, who had failed to form abscesses during recurrent life-threatening infections with gram positive and gram negative organisms [93]. A Rebuck skin window showed abnormal cellular migration. Although actin levels are normal in the affected neutrophils, the polymerization of actin is defective leading to poor or absent migration of neutrophils to the chemotactic stimuli. After the initial report, more children have been reported with neutrophil actin deficiency or its variants [94].

Allogeneic HCT has been attempted in a few patients with this disorder [95]. According to the published reports, one of three patients survived and was cured. The successfully treated patient received a high-dose regimen with BU, CY and ATG. The other two patients engrafted but died due to treatment-related complications, mainly infections. It is possible to correct the defect in neutrophil actin abnormality by HCT using a heterozygous histocompatible sibling donor. Since the disease course is very aggressive, supportive care alone is usually not sufficient to allow prolonged survival of these patients.

Leukocyte adhesion deficiency type I

First described in 1974, the leukocyte adhesion deficiency (LAD-1) is a rare heterogeneous autosomal recessive disorder in which neutrophil adhesion, chemotaxis and ingestion of the C3bi-opsonized microbes is impaired [96,97]. The neutrophils fail to migrate in the Rebuck skin window and also exhibit defects in neutrophil functions of adhesion and phagocytosis. It is usually detected in early childhood as a result of frequent, life-threatening bacterial and fungal infections, delayed umbilical cord separation and neutrophilia. The infections are mostly localized in the skin, subcutaneous tissues, middle ear, and oropharynx.

At the molecular level, the basic defect lies in the β_2 integrin adhesion molecule (CD11/CD18). The CD11/CD18 glycoprotein family consists of three heterodimeric proteins each composed of α and β chains. Translocation of α and β chains to the cell surface requires assembly of the $\alpha\beta$ heterodimer. The mutations in the CD11/18 deficiency have been found to be in the β_2 chain which prevent the assembly of the $\alpha\beta$ heterodimer and thereby translocation of the heterodimer to the cell surface [98]. The cells with the mutated glycoprotein are unable to adhere or migrate in response to chemotactic stimulation. Since the β_2 chain is constant for each family and is present on the surface of the leucocytes, flow cytometric analysis with pertinent monoclonal antibodies can help identify those affected by the disorder. The severe clinical phenotype with less than 0.3% of the normal amount of β_2 integrins is more commonly seen as compared to the moderate variant in which β_2 integrin levels of 2.5–11% of the normal are observed.

Since most of the children with leukocyte adhesion deficiency experience severe infections and die early in the course of their disease, early diagnosis and treatment, possibly with HCT, should be attempted. Several reports describe the course of HCT in patients with LAD-I. So far, 14 patients have been reported to have received HCT. Of these 14, five patients underwent HLA-matched sibling donor HCT, and nine patients received grafts from two antigen-mismatched or haplo-identical related donors [99,100]. In this study of 14 patients, the majority achieved either full or mixed chimerism. In most of the patients with mixed chimerism, a variable number of donor cells were noted with no increased incidence of infections except in one patient with 2–15% donor cells who developed mild gingivitis. Also, two patients with immunologic graft rejection achieved full chimerism after treatment with anti CD-2 or LFA-1 monoclonal antibody. There have been reports of successful unrelated HCT utilizing fully matched and one antigen-mismatched donors [101,102]. A recent report from Qasim et al. is the largest series of 36 children with leukocyte adhesion deficiency [103]. Myeloablative conditioning was used in 28 patients and RIC was used in eight patients. Survival rates after matched sibling donor and unrelated donor HCT were similar and mortality was highest with haplo-identical donors. Twenty-seven patients are alive with full donor engraftment in 17 patients and mixed chimerism in 10 patients. The study concluded that RIC was safe and mixed chimerisms were effective in preventing infections.

Beside CD11/18 deficiency, there are other leukocyte adhesion molecules called selectins. Defect in these molecules may result in significant disease. Two patients have been described with the absence of neutrophil receptors for E-selectin resulting in defective adhesion. This disorder is called LAD type II. To date, HCT has not been attempted in patients with selectin deficiency.

Chediak–Higashi syndrome

Chediak–Higashi syndrome (CHS) is an autosomal recessive disorder. Clinically, it is characterized by partial ocular and cutaneous albinism and an increased susceptibility to bacterial infections and compromised platelet function. Partial albinism and photophobia are usually noted in early infancy and increased susceptibility to respiratory and cutaneous infections soon become apparent. Decreased platelet function leads to bleeding tendency. Other organ systems involved include hair, adrenal glands, pituitary gland, and peripheral nerves [104]. The disease is manifested in two forms namely an initial stable phase followed by an accelerated phase. The stable phase disease may or may not be associated with serious infections while the accelerated phase disease may be complicated by fulminant infections and massive hepatosplenomegaly, lymphadenopathy, anemia, neutropenia, and thrombocytopenia [104,105]. The accelerated phase is uniformly fatal and no long-term survivors of the accelerated phase have been reported. In some patients the diagnosis of CHS is not apparent until the accelerated phase has developed.

Although phagocytosis per se occurs at a higher than normal rate in neutrophils, and post-phagocytic metabolic burst is also normal, the basic abnormality lies in the production of abnormal lysosomes and granule formation in cells of the myeloid cell series [106,107]. This abnormality leads to defective microbial killing and clinical manifestations of the CHS. The molecular defect has been reported to be an abnormal calcium uptake pump in CHS lysosomes resulting in an inefficient and incomplete post-phagocytic delivery of lysosomal enzymes into the phagosomes. This defect results in delayed intracellular destruction of bacteria by the Chediak–Higashi leukocytes [107]. In addition, cellular responses to chemotactic stimuli also appear to be defective.

In the laboratory, light and electron microscopy can be used to diagnose CHS by demonstrating abnormal granules and lysosomes. Neutrophils containing giant azurophilic granules along with abnormal lysosomes can be demonstrated. Monocytes and macrophages show abnormal lysosomes as well. Both lymphocytes and NK cells also have giant cytoplasmic granules with decreased NK function. In platelets, the content of dense granules is decreased leading to abnormal platelet function. The bone marrow examination of these patients displays ineffective myelopoiesis.

The first HCT procedure for CHS using a sibling donor was performed in a patient in accelerated phase [108]. CY alone was used as a preparative regimen. The patient, however, could not achieve sustained engraftment, probably due to inadequate preparation. The patient relapsed back into the accelerated phase and a second transplant procedure from the same donor was attempted. This time, however, a preparative regimen containing CY and TBI was used. This strategy resulted in stable engraftment. Another patient who was in the stable phase of the disease was similarly treated with CY and TBI resulting in full donor engraftment and correction of the functional defect [109]. A series of 10 other patients has been published [110]. Two patients were in stable disease and eight patients were in the accelerated phase of CHS. Seven patients received HCT from sibling donors and the other three received one antigen-mismatched or haplo-identical donor grafts. The preparative regimen included BU, CY and etoposide in eight patients. One patient received additional cytosine arabinoside. Three of the seven long-term survivors achieved full donor chimerism while four patients demonstrated mixed chimerism. In one patient with low level of donor chimerism, persistent bacterial infections were seen. As expected, in none of these patients were the cutaneous, ocular, and neurologic manifestations corrected.

A few reports describe patients receiving RIC leading to mixed chimerism with as low as 20% donor cells. These patients have continued [103] to do well without developing accelerated phase of the disease [111,112].

It is clear that HCT can be used successfully to treat patients with CHS in both stable as well as accelerated phase. HCT should be considered in the early stages as soon as the diagnosis is established. Patients with stable phase disease are expected to tolerate the procedure better than those treated in the advanced phase when serious organ damage might have taken place. If matched sibling donors are not available, unrelated donors can be considered. As evident from the earlier discussion, a good number of patients develop mixed chimerism in spite of the aggressive preparatory regimen used. Most of these mixed chimeric patients do not progress to the accelerated phase of CHS and continue to do well.

There are results from long-term follow-up of patients several years post-HCT. Eleven out of 20 patients who underwent HCT for CHS 20 years ago have shown signs of progressive neurological deterioration consistent with the progression of CHS [113] . Similar findings were also suggested by the earlier follow-up reports on patients with CHS [114].

Chronic granulomatous disease

Chronic granulomatous disease (CGD) is a rare clinical syndrome resulting from defective neutrophil function. Both autosomal recessive and X-linked patterns of inheritance have been described.

Although the carriers are usually asymptomatic, females with extreme "lyonization" may be affected. The median age at presentation of the disease is 7 years (range: 0.4 years to 15 years). Clinically, the course of CGD is extremely variable. Some patients present within their first year of life while others may present later. Most patients suffer from recurrent bacterial and fungal infections. Those presenting later in life may have fewer life-threatening infections than those who present early. The most common bacterial infections are from catalase-positive bacteria such as staphylococcus aureus and enteric bacilli. Aspergillus is the most common fungal infection. Infections are usually cutaneous, sinu-pulmonary and lymphadenitis. The occurrence of hepatic abscesses is characteristic in these patients. Serious and persistent infections may lead to formation of granulomas in vital organs.

In CGD, neutrophils are characterized by a defective respiratory burst formation during phagocytosis and an inability to generate superoxide. The impaired superoxide production usually occurs transiently in each phagosome and leads to recurrent bacterial and fungal infections. Those bacteria that have their own mechanism to produce hydrogen peroxide to generate hypochlorous acid (HOCl) via the myeloperoxidase pathway of the phagocytic killing pose little problem. However, microbes such as catalase-positive bacteria can produce very low amounts of hydrogen peroxide in the phagocytic vacuoles. This defect results in insufficient production of HOCl to contribute to significant bacterial killing culminating into recurrent infections with these bacteria [115].

The molecular basis of CGD has now been well defined. The respiratory burst defects have been found to be due to mutations in one of the four subunits of NADPH oxidase complex. Of the four subunits, two are membrane associated while the other two are located in the cytosol [115]. The gene for one of the membrane-associated subunits is located on the X chromosome, while the others are encoded by genes on chromosomes 1, 7, and 16. The disease is classified according to the underlying respiratory burst unit defect. In two large studies of 140 pediatric patients, defects in the X-linked gene for the gp91^{phox} subunit of cytochrome-b accounted for 62% of the cases. The remainder were found to be due to autosomal recessive defects in p47^{phox} (27%), p67^{phox} (5%), and p22^{phox} (6%). The nitrobluetetrazolium (NBT) test is a very important laboratory tool to detect the disease and also to detect the carrier state [116].

With the availability of excellent supportive care the overall survival of patients with CGD has improved with life expectancy extending into the 30-year range. Although prophylaxis with trimethoprim-sulphamethoxazole have improved the outcome in these patients [117–119], resistant fungal infections still pose significant life-threatening problems with resultant early mortality.

Allogeneic HCT may be appropriate in patients with frequent serious infections despite aggressive medical management. The availability of excellent supportive care with improved outcomes and the extreme variability in the disease course makes selection of appropriate patients for HCT very difficult. Pre-transplant evaluation is still of critical importance. The older patients are anticipated to have higher incidence of HCT-related complications including graft failure and/or rejection. Tissue damage due to chronic inflammation should be carefully evaluated. Hepatic abscesses, ileocecal inflammation, and gastrointestinal obstruction can influence the outcome of HCT. The patients should also be evaluated for other associated disease entities such as antibody negative collagen vascular disease, retinitis pigmentosa, Macleod red cell syndrome, and Duchenne muscular dystrophy. A significantly higher mortality in patients with the X-linked recessive form of the disease has been reported and should be considered while selecting the patients [120]. Also, the possibility of extreme "lyonization" should be kept in mind when considering related donors.

Allogenic transplantation has proven to be curative for patients with CGD and the number of reports of successful HCT in patients with CGD has increased during the past two decades [120–127]. Most of these HCT procedures have been performed using HLA-matched sibling or unrelated donors. With such donors, RIC preparative regimens containing CY or CY with anti-thymocyte serum were used initially. This resulted in expected autologous recovery with later recurrence of the disease. In one case, 1–2% cells from the donor could be identified for about 3 years after which time these cells also disappeared. This observation of autologous recovery suggested the necessity for using high dose conditioning. Subsequently, CGD patients were, therefore, treated with fludarabine and reduced doses of BU (8 mg/kg). This strategy has produced better outcomes resulting in mixed chimerism (10–23%) [128]. Horowitz et al. published their results on 10 patients with CGD who underwent matched sibling donor transplants with RIC and a T-cell-depleted graft [129]. The results of this study were mixed as six patients achieved 100% donor chimerism and two patients rejected the graft. Three patients died due to serious infections and GVHD.

To date, approximately 37 patients have been reported to the CIBMTR as having undergone transplant within the US and 55 in non-US centers. The overall survival at 1 year is 87% and at 3 years 83% for this group. Seventy-seven percent of these patients were transplanted at less than age 10 with 37% of the recipients less than 2 years of age. An additional 50 patients outside of the US and Canada are reported in various publications including single case reports and a survey of the European experience [130] with an overall survival rate of 94% and a success rate of 43 out of the 50 achieving stable donor engraftment. The longest reported follow-up to date from the Europeans is 5 years in a patient transplanted using a HLA-matched sibling and a BU/CY-based conditioning regimen. Similar to the US data, the majority of these patients are less than 10 years of age with only seven of the entire cohort being of age 18 or greater at the time of transplant.

The largest single reported group within the US was transplanted at the NIH, where a non-myeloablative regimen was used to treat 14 patients, including a number of adults. Two patients died due to GVHD, three patients had failure to engraft with one death as a result, and three had late graft rejection. Two patients have stable mixed chimerism, one of whom has only 43% lymphoid engraftment and 15% myeloid engraftment more than 6 years beyond his transplant but continues to be infection-free. We have also performed a second transplant in a young male who, despite a conditioning regimen consisting of Campath 1-H, melphalan, and fludarabine and four donor lymphocyte infusions, failed to maintain myeloid engraftment after a transplant using his HLA-matched sister as the donor. Using the same donor, the patient was treated with BU at 10 mg/kg, achieved 100% myeloid engraftment, and is now doing well at 3 years post-transplant [130].

Although the high dose regimens have led to more success in obtaining sustained hematopoietic reconstitution with long-term survival, the attendant increased risk of worsening infections and regimen-related toxicity cannot be ignored especially in older patients. Other complications of HCT in CGD patients include high risk of graft failure and increased risk of GVHD. Since the occurrence of repeated infections over a long period of time in the older patients may result in significant organ damage, it may predispose this patient population to higher risk of HCT-related complications such as GVHD. Therefore, active infections or inflammation should be attended in a timely and appropriate fashion as described later. The increased risk of GVHD in the CGD patients may possibly be due to the occurrence of repeated infections and/or inflammation resulting in sustained elevation of TNF-α levels in these patients [131,132]. Administration of TNFα-antagonists has been proposed to neutralize the circulating TNF-α. A study of 27 CGD patients has been reported evaluating complications (including GVHD) and survival according to different risk factors (infection and/or inflammation) present at the time of HCT [132]. Twenty-five patients received the graft from a compatible sibling donor and the remaining two patients received their HCT from HLA-matched unrelated donors. All patients were treated with high dose conditioning. In this study an overall survival of 23/27 had been reported with 22/23 patients cured of CGD (median follow-up of 2 years). Moreover, a slightly higher incidence of severe GVHD (grade III–IV) was found in those patients who had pre-existing overt infections and/or active inflammatory conditions prior to the HCT (4/11 patients). Of the 16 patients who did not have any overt infection/inflammation, only three patients developed mild grade II GVHD. Also, the high dose conditioning used in the study did not pose a problem in the majority of the patients who did not have pre-existing infections [133]. It is, therefore, important to identify the presence and nature of the infected foci clinically, by laboratory means and by using the appropriate radiological methods such as computed tomography (CT), positron emission tomography (PET), and combined PET/CT to institute appropriate therapy [134]. The active infections/inflammation should be treated adequately using antimicrobials with intracellular action. This aggressive treatment should be carried out before and during the HCT procedure.

In conclusion, patients with CGD can be cured with sibling donor or unrelated donor HCT. However, overall outcome is superior with the sibling donor transplants. Pre-transplant evaluation of patients with severe disease and treatment of active infections and inflammation prior to and during HCT plays an important role in the overall outcome of CGD patients. Optimal conditioning regimen includes complete myeloablation to prevent autologous recovery and immunosuppression to prevent GVHD in order to attain good results.

Since CGD results from single gene defects in proteins expressed in myeloid cells, this disorder can be considered as an excellent candidate for gene replacement therapy targeted to the hematopoietic cells. Gene replacement therapy can be theoretically very useful in patients with as few as 10–20% NBT positive cells. This concept is supported by the fact that the female carriers in the X-linked variant of CGD have as low as 10% NBT positive cells and are asymptomatic. So far, successful gene therapy had been limited to in vitro experiments where reconstitution of the respiratory burst activity has been displayed in Epstein-Barr virus-transformed lymphocytes [135]. The in vivo clinical attempts to mediate gene transfer into long-lived human hematopoietic cells have met with a lack of availability of appropriate viral vectors to carry out gene transfer.

Griscelli syndrome

Griscelli syndrome (GS) is an autosomal recessive disorder that affects both lymphoid and myeloid cells. The basic defect in Griscelli syndrome is characterized by lymphoid and NK-cell dysfunction with clinical manifestations of partial albinism with immunodeficiency [136,137]. The disorder is uniformly fatal and is also characterized by an abnormal regulation of the immune system resulting in an accelerated lymphohistiocytic phase along with macrophage hyperactivation as seen in HLH. Variable granulocyte dysfunction may coexist. Two different gene loci, *RAB27A* and *MYO5A*, have been identified in patients with GS [138]. Unlike *MYO5A*, the GTP-binding protein *RAB27A* is involved in the control of immune regulation and appears to be a key effector of cytotoxic degranulation. Also, all patients with GS who have mutations in the *RAB27A* gene have developed HLH.

A systematic diagnostic approach is very essential in suspected cases of GS. The diagnostic steps should include clinical, laboratory and histopathologic assessment as mentioned in diagnostic guidelines for HLH. The NK-cell activity should also be tested. Finally, mutation analysis of *RAB27A* gene should also be performed to confirm the diagnosis. This systematic approach is very important to identify those patients who have a worse prognosis and need timely intervention with the HCT.

Allogeneic HCT is the only potentially curative treatment of choice in GS. Although the data are limited due to the rarity of the disease, several reports of HCT performed in GS patients using sibling, matched related as well as matched unrelated donors exist [139]. In one report of three patients who received HLA-matched sibling graft two patients died due to transplant-related complications [139]. The third patient achieved full chimerism with normal immune and hematopoietic function and had done very well post-HCT procedure. In another published case of a six-month-old patient with Griscelli syndrome, mobilized peripheral blood hematopoietic cells from her phenotypically HLA-identical mother were used [140]. In this patient, the conditioning included BU, CY and etoposide. The patient received a $CD34^+$ cell dose of 15.4×10^6/kg along with the $CD3^+$ cell dose of 17.6×10^3/kg recipient body weight. Three months after the transplant procedure was performed, a lymphoproliferative syndrome occurred and was successfully treated. Twenty-six months after HCT, the patient has shown mixed chimerism (52% donor cells) and is well. A recent case report has shown successful HCT in a patient with GS using a matched unrelated donor graft [141]. In this patient, high doses of BU were used along with thiotepa and fludarabine as conditioning prior to the HCT. The number of nucleated cells infused was 7.8×10^8/kg of recipient body weight. Engraftment in this patient was prompt and the patient is well 30 months post-HCT with complete donor chimerisms and normal full blood cell counts.

In summary, in addition to a systematic diagnostic approach, an early intervention with HCT in GS patients with *RAB27A* gene mutation is recommended. If a sibling donor is not available an immediate search for an unrelated donor should be performed. If no histocompatible donors are available, strong consideration for an unrelated donor or haplo-identical HCT should be given as the condition is rapidly fatal.

Osteoclast disorders

Osteopetrosis (OP) is a rare metabolic bone disease characterized by a generalized increase in skeletal mass. The defect results in poor functioning osteoclasts leading to impaired bone resorption that prevents formation of bone marrow cavities. It is a heterogeneous group of disorders and the first description of a patient with increased bone density was by Albers-Schonberg in 1904 [142]. Since then a number of disorders with osteoclast dysfunction have been described and further knowledge has been gained by osteopetrotic mice and other animals. The disorder can be inherited in either autosomal recessive or dominant fashion and may vary in severity from a disease that may kill infants to an incidental radiological finding in adults [143].

Aberrant resorption and remodeling of the bone caused by defective osteoclast function can result in many potential clinical consequences:

- Fractures: bones are undertubulated so they break easily. Common fracture sites are long bones.
- CNS and eye problems: bony overgrowth or lack of remodeling results in compression of nerves or blood vessels that pass through bones especially the optic nerve leading to blindness.
- Pancytopenia due to encroachment of the medullary cavity results in extramedullary hematopoiesis.
- Growth: most children will have short stature.
- Hypocalcemia due to disturbance in calcium homeostasis.
- Poor dentition [143].

Overall there seems to be a considerable amount of variability in all forms of OP. Malignant infantile OP is often the disease with autosomal recessive inheritance that presents under the age of 2 years. Children presenting after age 2 generally have a slower progressive disease.

Until year 2000 only one causative gene was known but since than eight other genes have been identified. In 25% of children with autosomal recessive inheritance the exact genetic mutation is still unknown [144].

Table 75.3 shows the classification of OP by genetic inheritance, molecular basis, and possible response to HSCT [144].

The main agents used in the management are calcitrol, prednisone, and interferon. Neither of these agents is proven to be of benefit in the long run. The history of HCT dates back to a series of experiments performed by Donald Walker on mice. These experiments led to the first attempted unconditioned HCT in France in 1977, with some transient benefit but no documented donor engraftment. In 1980, Coccia and colleagues reported successful engraftment of a patient using HLA-identical marrow after cyclophosphamide therapy and modified total body radiation [145]. Unfortunately this patient had a slow rejection of the graft.

Table 75.3 Classification of osteopetrosis (OP)

Causative gene/protein product	OC rich or poor on bone biopsy	Frequency within AR OP (%)	Good response to HSCT
ATP6i (TCIRG1) (proton pump)	Rich	50	Yes
CICN7 (chloride channel)	Rich	15	Yes, but contraindicated in neuronopathic forms; late CNS pathology may occur
OSTMI	Rich	5	Contraindicated as neuronopathic disease not alleviated
TNFSF11 (RANKL)	Poor	3	Contraindicated as not caused by an intrinsic osteoclast defect
TNFRSF11A (RANK)	Poor	3	Yes, but long-term neurologic prognosis uncertain
CA2 (carbonic anhydrase II)	Rich	Not reported	Probably contraindicated; neurologic follow-up of patients reported in Ref. 15 awaited
PLEKHM1	Rich	<1	Not needed, mild form of OP
Kindlin-3	Not reported	<1	Not known
NEMO	Rich	<1	Not known
Unknown	Rich or poor	20–25	Not evaluable

RANK, receptor activator NF-κB; RANKL, receptor activator NF-kB ligand.

The largest reports on HCT for OP come from the European Group for Blood and Marrow Transplantation (EBMT) [146]. The reports are on 69 and 122 patients with some overlap. Five-year survival for sibling donors is considerably higher (73–79%) as compared to the unrelated donor group (13–43%). Most patients received the conditioning with BU and CY. Primary and late rejection rates seem to be higher. Other complications were neuropathic (in patients with neuropathic disease and post-transplant hypercalcemia [147]). In patients with ATP6i mutations the incidence of pulmonary hemorrhage and respiratory failure was high [148]. Many children have a decent quality of life, however, a decline in visual acuity may continue for years to come [149].

Because of the problems with non-engraftment and late rejections, especially in cases with unrelated donors, European groups have tried to increase the conditioning to include Thiotepa and ATG. These patients received the mega dose CD34$^+$ cells from the donor with some encouraging results [144].

It is recommended that there should be a very detailed pre-transplant work-up of the genetic mutations and associated defects including X-ray of extremities, magnetic resonance imaging of head and chest, and a detailed ENT and ophthalmic examination. Patients with autosomal recessive disease should be investigated immediately for TCIRG1 and CACN7 mutations. TCIRG1-mutated patients should be considered for transplantation as soon as possible [144]. The decision for transplantation should be made with the family after careful discussions about long-term neurologic issues that can arise. Disease-free HLA-identical siblings are the donors of choice and in the unrelated donor setting high doses of selected CD34$^+$ cells may be considered. Bone may take about 12 months or more to normalize even after full donor engraftment and hypercalcemia is a risk that needs management in most patients.

Conclusion

Allogeneic HCT remains the procedure of choice for most of the diseases discussed in this chapter. An HLA-matched sibling is the preferred donor. However, if such a sibling is unavailable, a search for a histocompatible matched unrelated or haplo-identical related donor should not be delayed. In specific cases such as X-linked CGD with severely imbalanced "lyonization" or in primary HLH, the risk–benefit ratio should be assessed before choosing a sibling versus an unrelated donor. Early diagnosis and HCT is essential in some of the disorders such as leukocyte adhesion deficiency and Chediak–Higashi syndrome due to the aggressive and fatal nature of these disorders. An efficient pre-transplant evaluation is, therefore, important.

The outcome of HCT in macrophage–phagocytic disorders has improved during the last decade. In addition to high-quality supportive care after HCT and improved GVHD prevention, the factors that affect a successful outcome with HCT include a careful early diagnosis, nature or course of the disease, pre-existing serious infections, other pre-existing comorbidities, and the status of vital organ functioning at transplantation.

CHAPTER 76

Hematopoietic Cell Transplantation for Fanconi Anemia

Introduction

Fanconi anemia (FA) is a genetically and phenotypically heterogeneous autosomal and X-linked recessive disorder characterized by congenital malformations, progressive marrow failure, and marked predisposition to malignancy. The prevalence of FA is greater than one in 100,000 births, with carrier frequencies ranging from 1 in 200 generally to greater than 1 in 100 in persons of Ashkenazi Jewish or South African Afrikaans descent, due to founder effects in these populations [1–4]. While the exact basic biochemical defects responsible for the syndrome are not completely elucidated, animal models and longitudinal studies evaluating the phenotypic consequences of specific mutations provide important clues about the function of FA genes and the care of patients with this disorder. In this chapter, the pathogenesis and pathology, diagnosis and treatment of FA will be reviewed with particular emphasis on the expected results of allogeneic hematopoietic cell transplantation (HCT). As of 2015, allogeneic HCT remains the only treatment modality with the proven potential of correcting the hematologic defect common to most patients with FA.

Early history

In l927, Fanconi described a family in which three male children between the ages of 5 and 7 years had pancytopenia and birth defects [5]. Based on his observations in this family and others, Fanconi's chief criteria for the diagnosis of FA were pancytopenia, hyperpigmentation, skeletal malformations, small stature, urogenital abnormalities, and familial occurrence. According to Fanconi, Naegeli suggested in 1931 that the term "Fanconi's anemia" be used to describe such patients [6]. Fanconi's proposed diagnostic criteria for FA were widely accepted well into the 1980s. Consideration of FA in the differential diagnosis of a patient manifesting clinical features of the syndrome depends on the clinician's concept of the FA phenotype. Most cases reported in textbooks and in the literature prior to the present decade present a clinical picture similar to that of the original cases described by Fanconi. Diagnosis of FA was usually made when aplastic anemia (AA) or leukemia developed in individuals with the characteristic physical abnormalities. Literature reviews have thus been biased, more likely excluding those without the "classic" phenotype. Glanz and Fraser [7], however, were among the first to report that the phenotype was quite variable. Compared to probands, affected siblings were more likely to have a milder phenotype, being diagnosed only after the diagnosis of FA in another affected family member and not because of their phenotypic presentation. In addition, patients with "Fanconi-like" marrow failure who completely lacked congenital malformations, previously described as having the Estren–Dameshek syndrome [8], were found in the same sibships with "classical" FA. While there is increasing awareness of the immense heterogeneity with regard to malformations and stature, the correct diagnosis is often delayed until the onset of marrow failure regardless of race or presence of congenital malformations [9,10].

Clinical features

The FA phenotype is extremely variable. FA patients can be developmentally normal or can have such severe abnormalities that there is spontaneous abortion or perinatal death [11]. The majority (60–70%) of FA patients have at least one congenital malformation with the classic being radial ray defects, ranging from a mildly hypoplastic thenar eminence and tapered thumb to complete absence of the thumb and radius. Abnormalities, however, can involve any of the major organ systems (Table 76.1). To maximize the chance of correct diagnosis, the clinician must first recognize the plethora of malformations possible in FA as well as the phenotypic overlap with other syndromes. For example, FA patients frequently present with ***v***ertebral anomalies, ***a***nal atresia, ***c***ardiac abnormalities, ***t***racheo-***e***sophageal fistula, ***r***enal anomalies, and radial ***l***imb and are therefore labeled as VACTERL syndrome. FA patients may also present with a phenotype characteristic of Holt–Oram syndrome, thrombocytopenia absent radius (TAR) syndrome, Baller–Gerold syndrome, Saethre–Chotzen syndrome (TWIST mutation), Dubowitz syndrome, velocardiofacial syndrome, Diamond–Blackfan anemia, dyskeratosis congenita, Seckel syndrome, and Nijmegen breakage syndrome. The clinician must not be misled by preexisting "diagnostic labels." Unless DNA cross-linking hypersensitivity has been ruled out (discussed later), FA is still the possible correct diagnosis. Such mislabeling is very common prior to the onset of marrow failure, resulting in suboptimal care and marrow surveillance as well as inaccurate reproductive counseling.

The International Fanconi Anemia Registry (IFAR) was established at The Rockefeller University in 1982 to collect clinical,

genetic and hematologic information from a large number of FA patients over time in order to understand the full spectrum of clinical features and natural history of the disease. Based on the clinical information in the IFAR, congenital malformations associated with FA are even more variable than previously recognized [10]. For example, radial ray abnormalities in FA patients can be bilateral or unilateral. Even patients with bilateral abnormalities usually exhibit asymmetry, with limbs having different specific anomalies. Moreover, nearly one third of FA patients do not manifest any major congenital malformation. However, to the trained practitioner most FA patients will have short stature relative to the rest of the family, skin pigmentation abnormalities, hypoplasia of the thenar eminence bilaterally, and microophthalmia. Increased awareness of the complete spectrum of minor malformations observed in these patients should enable an earlier diagnosis even in the absence of marrow failure [11].

Table 76.1 List of congenital malformations in Fanconi anemia (FA)

Congenital malformation	Frequency (%)
Skin pigmentation (café-au-lait spots, hyper- and hypopigmentation)	71
Thumb and radius (thenar hypoplasia, clinodactyly of fifth digit, syndactyly of fingers, hyperextensible thumbs, arachnodactyly, absence or hypoplasia of radius)	59
Skeletal (dysplastic ulna, micrognathia, frontal bossing, spina bifida, Klippel–Feil syndrome, vertebral anomalies, Sprengel deformity)	31
Kidney and urinary tract (ectopic, horseshoe, rotated, hypoplastic or absent, dysplastic, hydronephrosis, hydroureter, reflux)	57
Genital (*males*: micropenis, undescended or atrophic or absent testes, hypospadius, phimosis, azospermia; *females*: bicornate uterus, aplasia or hypoplasia of vaginaand uterus, atresia of vagina, uterus and ovary)	50 (males)
Cardiac (patent ductus arteriosis, ventricular septal defect, pulmonic or aortic stenosis, coarcation of the aorta, double aortic arch, cardiomyopathy, tetralogy of Fallot)	29
Ears [deafness (usually conductive), atresia or dysplasa, canal stenosis]	Unknown
Eyes (microophthalmia, short or almond-shaped palpebral fissures, ptosis, epicanthal folds, hyper- and hypo-telorism)	47
Nose (flattened nasal bridge, nasal pit)	1
Gastrointestinal (esophageal atresia, duodenal atresia, anal atresia)	7
Central nervous system (CNS) (microcephaly, hydrocephalus, Bell's palsy, CNS arterial malformations, abnormal pituitary, absent corpus callosum, hyperreflexia)	1
Growth retardation (short stature)	67

Importantly, there is phenotypic variation even between siblings affected with FA. Among 53 sibships composed of 120 siblings, there was considerable variation in malformations. Even between two sets of monozygotic twins, there was phenotypic discordance [12]. While there is concordance in the presence or absence of congenital malformations between siblings, the variable expressivity even between twins underscores the need to test all siblings of a child (or adult) with FA since the absence of a major malformation itself does not rule out FA.

Short stature is particularly common in FA and is often secondary to hormonal deficiencies. The syndrome is usually associated with abnormal growth parameters both prenatally and postnatally (Figure 76.1) with most having a height, weight, and head circumference at the 5th centile based on reports in the IFAR database. However, growth may be improving in the past decade, perhaps as a result of more intensive monitoring and nutrition. In a recent study by Rose et al. [13], 43% of FA children were within two standard deviations of the 50th centile with 9% above the mean height for the general population. Still, most children and adults with FA had one or more endocrine abnormalities. In another study, 54 patients with FA (30 males and 24 females from 47 unrelated families) were evaluated for endocrinopathies prospectively. In this study, the most common manifestations of endocrinopathy were glucose/insulin abnormalities, growth hormone insufficiency, and hypothyroidism [14]. Expectedly, patients with endocrine dysfunction are more likely to have short stature with other endocrinopathies magnifying the degree of growth failure. Since correction of growth hormone or thyroid hormone deficiency may improve final height outcome and quality of life, a comprehensive evaluation is recommended for all FA children at an early age well before HCT or the use of androgens when possible.

Gonadal failure and infertility are also common. Approximately half of all female patients with FA are infertile. Delayed menarche and premature menopause (often in the fourth decade) are common. Still, 15% of females cited in the literature or reported to

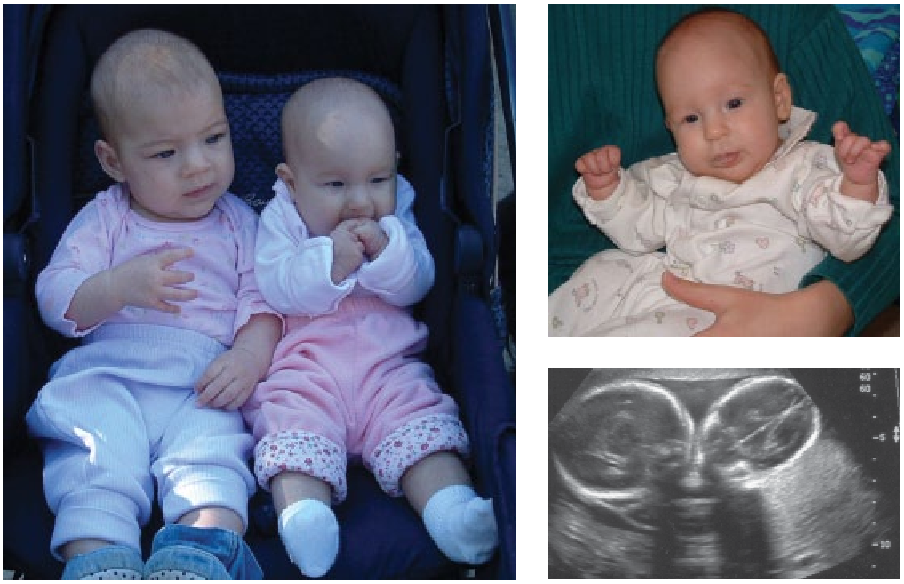

Figure 76.1 Nine-month-old twins; one healthy and one affected by Fanconi anemia (FA). Photographs demonstrate the "classical" physical features associated with FA, specifically growth retardation, bilateral hypoplastic radii, and absent thumbs, microophthalmia, and microcephaly.

the IFAR who reached 16 years of age and were not receiving androgen therapy had at least one pregnancy [15]. While pregnancy is possible in some females, it is often associated with rapid progression to severe marrow failure with transfusion dependence as well as preeclampsia and premature labour, underscoring the importance of reproductive counseling. In contrast, males are very rarely if ever fertile [16]. Genital malformations, hypoplastic gonads and low or absent sperm counts, are common findings in males with FA. Because of the high incidence of gonadal failure and its effect on growth and development as well as bone density, estrogen and testosterone levels should be routinely monitored.

Hematologic abnormalities occur in most patients with FA at a median age of 7 years (range: birth to 41 years) (Figure 76.2) [17–19]. Based on clinical data in the IFAR (*n* = 754 patients), the incidence of bone marrow failure is 90% by the age of 40 years. Although less often today due to more accurate diagnosis and enhanced monitoring, occasionally patients still present with myelodysplastic syndrome (MDS) or acute leukemia without prior diagnosis of AA. Historically, the incidence of MDS or acute leukemia in the IFAR has been 33% by the age of 40 years [18] (Figure 76.3). Similar results have been reported by Rosenberg et al. based on a survey of FA patients in North America with the median age of onset of leukemia being 11.3 years [20]. Annual marrow examinations, however, have led to earlier diagnosis of MDS and clonal cytogenetic abnormalities, in turn resulting in earlier HCT prior to disease progression. The development of clonal cytogenetic abnormalities

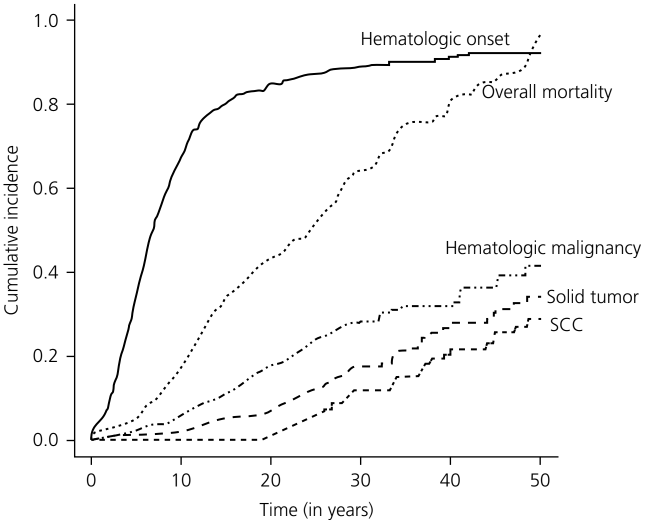

Figure 76.2 Cumulative incidence of hematologic abnormalities and malignancy over time in patients with FA. Of 754 FA patients within the International Fanconi Anemia Registry (IFAR) database, 601 (80%) experienced bone marrow failure, 120 (60%) hematologic malignancy, and 79 (40%) were non-hematologic malignancy. The risk of developing BMF and hematologic and non-hematologic malignancies increased with advancing age with a 90%, 33%, and 28% cumulative incidence, respectively, by 40 years of age. Figure 76.4 Upper panel: G-banded karyotypes from an abnormal clone in the marrow of an FA patient. This is a hyperdiploid metaphase cell with 48 chromosomes including two extra derivative chromosomes (designated by arrows); one derivative chromosome is composed of two copies of the long arm of chromosome 1 and the other contains two copies of a small portion of the long arm of chromosome 3. This cell contains a total of four copies of portions of chromosomes 1 and 3. Lower panel: A karyotype of the same abnormal clone as above, as characterized by fluorescent in situ hybridization (FISH) using a multicolor paint probe (Vysis spectral vision M-FISH). M-FISH confirmed that the two derivative chromosomes detected by G-banding represented extra copies of portions of chromosomes 1 and 3. Source: Courtesy Betsey Hirsch PhD. (For a color version of this figure, please see the color plate section.)

is increasingly more common with age. Historically, the actuarial risk of identifying clonal cytogenetic abnormalities is 67% by the age of 30 years; however, this includes patients in an era when annual marrow examinations were not the rule. Among the most frequent clonal abnormalities observed are duplications and triplications of the long arm of chromosome 1, gains of portions of the long arm of chromosome 3, and monosomy 7 or loss of material from the long arm of chromosome 7 [21]. Deletions of 5q, 11q, rearrangements of 6p and gains of chromosomes 8 and 21 have also been noted by different groups (Figure 76.4) [19,22]. In addition, acute myeloid leukemia (AML) in FA patients rarely involves the chromosomal rearrangements commonly observed in non-FA patients with AML (e.g., t[9;11], t[8;21], t[6;9], t[11;19], inv 6) and is often complex. Thus, many of the early descriptions of these karyotypes included designations of "marker" or "add," referring to structurally abnormal chromosomes that could not be completely identified by G- or R-banding. Recent advances in single and multicolor fluorescence in situ hybridization (FISH) and utilization of these and other molecular/cytogenetic techniques as adjuncts to conventional cytogenetic analysis now permits more definitive characterization of clones with the possibility of identifying new specific recurrent abnormalities (Figure 76.4). In the absence of myelodysplastic changes, leukemia or a severe cytopenia, the presence of a clonal cytogenetic abnormality in a proportion of the
